Guidelines and recommendations developed and/or endorsed by the American College of Rheumatology (ACR) are intended to provide guidance for particular patterns of practice and not to dictate the care of a particular patient. The ACR considers adherence to the recommendations within this guideline to be voluntary, with the ultimate determination regarding their application to be made by the physician in light of each patient's individual circumstances. Guidelines and recommendations are intended to promote beneficial or desirable outcomes but cannot guarantee any specific outcome. Guidelines and recommendations developed and endorsed by the ACR are subject to periodic revision as warranted by the evolution of medical knowledge, technology, and practice. ACR recommendations are not intended to dictate payment or insurance decisions, and drug formularies or other third-party analyses that cite ACR guidelines should state this. These recommendations cannot adequately convey all uncertainties and nuances of patient care.

The American College of Rheumatology is an independent, professional, medical and scientific society that does not guarantee, warrant, or endorse any commercial product or service.

Objective. To provide evidence-based recommendations and expert guidance for the management of antineutrophil cytoplasmic antibody–associated vasculitis (AAV), including granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis (EGPA).

Methods. Clinical questions regarding the treatment and management of AAV were developed in the population, intervention, comparator, and outcome (PICO) format (47 for GPA/MPA, 34 for EGPA). Systematic literature reviews were conducted for each PICO question. The Grading of Recommendations Assessment, Development and Evaluation methodology was used to assess the quality of evidence and formulate recommendations. Each recommendation required ≥70% consensus among the Voting Panel.

Results. We present 26 recommendations and 5 ungraded position statements for GPA/MPA, and 15 recommendations and 5 ungraded position statements for EGPA. This guideline provides recommendations for remission induction and maintenance therapy as well as adjunctive treatment strategies in GPA, MPA, and EGPA. These recommendations include the use of rituximab for remission induction and maintenance in severe GPA and MPA and the use of mepolizumab in nonsevere EGPA. All recommendations are conditional due in part to the lack of multiple randomized controlled trials and/or low-quality evidence supporting the recommendations.

Conclusion. This guideline presents the first recommendations endorsed by the American College of Rheumatology and the Vasculitis Foundation for the management of AAV and provides guidance to health care professionals on how to treat these diseases.

INTRODUCTION

The antineutrophil cytoplasmic antibody (ANCA)–associated vasculitides (AAV) comprise granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis (EGPA). These diseases affect small- and medium-sized vessels and are characterized by multisystem organ involvement.

GPA is characterized histologically by necrotizing granulomatous inflammation in addition to vasculitis. Common clinical manifestations include destructive sinonasal lesions, pulmonary nodules, and pauci-immune glomerulonephritis. GPA is most commonly associated with cytoplasmic ANCA and antibodies to proteinase 3 (PR3). Among European populations, prevalence ranges from 24 to 157 cases per million, with the highest prevalence reported in Sweden and the UK (1).

MPA is characterized histologically by vasculitis without granulomatous inflammation. Common clinical manifestations include rapidly progressive pauci-immune glomerulonephritis and alveolar hemorrhage. MPA is most commonly associated with perinuclear ANCA and antibodies to myeloperoxidase. The prevalence of MPA ranges from 0 to 66 cases per million among European countries and 86 cases per million in Japan (1,2).

EGPA is characterized histologically by eosinophilic tissue infiltration in addition to vasculitis. Common clinical manifestations include asthma, peripheral eosinophilia, and peripheral neuropathy. Only 40% of patients produce detectable ANCA. The overall prevalence of EGPA in European populations has been estimated to range from 2 to 38 cases per million (1,3).

Prior to the use of alkylating agents, survival with these diseases was quite poor (e.g., median survival of patients with GPA was ~5 months) (4). Current treatment regimens have reversed this poor prognosis, but treatments are still associated with toxicity. Recent clinical trials have investigated the efficacy and toxicity of both biologic and nonbiologic immunosuppressive agents for the treatment of AAV. Observational studies have provided additional insight regarding management strategies for these diseases. Therefore, this guideline was developed to provide evidence-based recommendations for the treatment and management of GPA, MPA, and EGPA. Although this guideline may inform an international audience, these recommendations were developed considering the experience with and availability of treatment and diagnostic options in the US.

METHODS

This guideline followed the American College of Rheumatology (ACR) guideline development process (https://www.rheumatology.org/Practice-Quality/Clinical-Support/Clinical-Practice-Guidelines) using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) methodology to rate the quality of evidence and develop recommendations (5,6). ACR policy guided the management of conflicts of interest and disclosures (https://www.rheumatology.org/Practice-Quality/Clinical-Support/Clinical-Practice-Guidelines/Vasculitis). Supplementary Appendix 1 (available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24634/abstract) presents a detailed description of the methods. Briefly, the Literature Review team undertook systematic literature reviews for predetermined questions addressing specific clinical populations, interventions,

The article is published simultaneously in *Arthritis & Rheumatology*.

comparators, and outcomes (PICO). An in-person Patient Panel of 11 individuals with different types of vasculitis (4 patients with GPA, 1 patient with MPA, and 2 patients with EGPA) was moderated by a member of the Literature Review team (ABD). This Patient Panel reviewed the evidence report (along with a summary and interpretation by the moderator) and provided patient perspectives and preferences. The Voting Panel comprised 9 adult rheumatologists, 5 pediatric rheumatologists, and 2 patients; they reviewed the Literature Review team's evidence summaries and, bearing in mind the Patient Panel's deliberations, formulated and voted on recommendations.

The Voting Panel was assembled for the ACR and Vasculitis Foundation's broad effort to develop recommendations for 7 forms of systemic vasculitis: giant cell arteritis, Takayasu arteritis, polyarteritis nodosa, Kawasaki syndrome, and the 3 AAVs presented in this report. The physicians on this panel included rheumatologists who could provide insight on all of these diseases and did not include other subspecialists who would not have experience with many of the other vasculitides addressed in this effort (e.g., pulmonologists who would not have experience with large- or medium-sized vessel vasculitis). The Literature Review team chair was a nephrologist. The patients on the Voting Panel presented the views of the Patient Panel, which consisted of patients with different types of vasculitis. A recommendation required ≥70% consensus among the Voting Panel.

How to interpret the recommendations

A *strong* recommendation is usually supported by moderate- to high-quality evidence (e.g., multiple randomized controlled trials). For a strong recommendation, the recommended course of action would apply to all or almost all patients. Only a small proportion of clinicians/patients would not want to follow the recommendation. In rare instances, a strong recommendation may be based on very low– to low-certainty evidence. For example, an intervention may be strongly recommended if it is considered benign, low-cost, without harms, and the consequence of not performing the intervention may be catastrophic. An intervention may be strongly recommended against if there is high certainty that the intervention leads to more harm than the comparison with very low or low certainty about its benefit (7).

Table 1. Definitions of selected terms used in the recommendations and ungraded position statements for GPA, MPA, and EGPA*

Term	Definition
Disease states	
Active disease	New, persistent, or worsening clinical signs and/or symptoms attributed to GPA, MPA, or EGPA and not related to prior damage
Severe disease	Vasculitis with life- or organ-threatening manifestations (e.g., alveolar hemorrhage, glomerulonephritis, central nervous system vasculitis, mononeuritis multiplex, cardiac involvement, mesenteric ischemia, limb/digit ischemia)
Nonsevere disease	Vasculitis without life- or organ-threatening manifestations (e.g., rhinosinusitis, asthma, mild systemic symptoms, uncomplicated cutaneous disease, mild inflammatory arthritis)
Remission	Absence of clinical signs or symptoms attributed to GPA, MPA, or EGPA, on or off immunosuppressive therapy
Refractory disease	Persistent active disease despite an appropriate course of immunosuppressive therapy
Relapse	Recurrence of active disease following a period of remission
Treatments	
IV pulse GCs	IV methylprednisolone 500–1,000 mg/day (adults) or 30 mg/kg/day (children; maximum 1,000 mg/day) or equivalent for 3–5 days
High-dose oral GCs	Prednisone 1 mg/kg/day (adults; generally up to 80 mg/day) or 1–2 mg/kg/day (children; generally up to 60 mg/day) or equivalent
Remission induction therapy	
Methotrexate	Up to 25 mg/week (SC or oral)
Azathioprine	Up to 2 mg/kg/day
Mycophenolate mofetil	Up to 1,500 mg (oral) twice per day
Cyclophosphamide	Up to 2 mg/kg/day (oral) for 3–6 months; or intermittent 15 mg/kg (IV) every 2 weeks for 3 doses, followed by 15 mg/kg (IV) every 3 weeks for at least 3 doses (adults)
Rituximab	375 mg/m^2 (IV) weekly for 4 doses or 1,000 mg on days 1 and 15 (adults); or 375 mg/m^2 (IV) weekly for 4 doses or 575 mg/m^2 for patients with body surface area ≤1.5m^2 or 750 mg/m^2 for patients with body surface area >1.5m^2 with a typical maximum of 1 gm per infusion (both for 2 doses, days 1 and 15) (children)
Mepolizumab	300 mg (SC) every 4 weeks (adults)
Remission maintenance therapy	
Methotrexate, azathioprine, mycophenolate mofetil	Same dosing regimen as in remission induction therapy
Rituximab	500 mg (IV) every 6 months or 1 gm (IV) every 4 months (adults), 250 mg/m^2 (IV) every 6 months (children), or other doses
Mepolizumab	300 mg (SC) every 4 weeks
Omalizumab	300–600 mg (SC) every 2–4 weeks

* GPA = granulomatosis with polyangiitis; MPA = microscopic polyangiitis; EGPA = eosinophilic granulomatosis with polyangiitis; IV = intravenous; GCs = glucocorticoids; SC = subcutaneous.

A *conditional* recommendation is usually supported by lower-quality evidence or a close balance between desirable and undesirable outcomes. For a conditional recommendation, the recommended course of action would apply to the majority of the patients, but the alternative is a reasonable consideration. Conditional recommendations always warrant a shared decision-making approach. We specify some conditions under which the alternative may be considered.

In some instances, the committee found that the evidence for a particular PICO question did not support a graded recommendation or did not favor one intervention over the other. However, the Voting Panel believed that the PICO question addressed a commonly encountered clinical question and thus felt that providing guidance for this question was warranted. For these situations, we present "ungraded position statements," which reflect general views of the Voting Panel.

In this evidence-based guideline, we explicitly used the best evidence available and present it for the clinician and reader (8). In some instances, this includes randomized trials in which the interventions under consideration are directly compared. The GRADE system rates evidence that comes exclusively from the collective experience of the Voting Panel and Patient Panel members as "very low quality" evidence (6).

For each recommendation, details regarding the PICO questions and the GRADE evidence tables can be found in Supplementary Appendix 2 (http://onlinelibrary.wiley.com/doi/10.1002/acr.24634/abstract).

RESULTS

For the evidence report for GPA and MPA, the Literature Review team reviewed 729 articles to address 47 PICO questions. For the evidence report for EGPA, 190 articles were reviewed to address 34 PICO questions.

Recommendations and ungraded position statements for GPA and MPA

GPA and MPA are recognized as different diseases for which disease-specific management approaches exist. However, many recommendations and ungraded position statements consider GPA and MPA together, because pivotal trials have enrolled both groups and presented results for these diseases together. Therefore, we present recommendations and ungraded position statements applicable to both GPA and MPA as well as recommendations and ungraded position statements only applicable to GPA. All recommendations for GPA/MPA are conditional, due in part to a lack of multiple randomized controlled trials supporting the recommendations. The complete list of studies reviewed to form the recommendations is provided in the evidence report (Supplementary Appendix 2, http://onlinelibrary.wiley.com/doi/10.1002/acr.24634/abstract). Given that these diseases affect multiple organ systems, collaboration between rheumatologists, nephrologists, pulmonologists, and otolaryngologists can enhance the care of patients with GPA and MPA.

Table 1 presents the definitions of selected terms used in the recommendations and ungraded position statements, including the definition of severe and nonsevere disease and the dosing regimens of medications used for remission induction and maintenance. Table 2 presents the recommendations and ungraded position statements with their supporting PICO questions and levels of evidence. Figure 1 presents key recommendations for the treatment of GPA and MPA.

Remission induction for active, severe disease

Recommendation: For patients with active, severe GPA/MPA, we conditionally recommend treatment with rituximab over cyclophosphamide for remission induction.

Both rituximab and cyclophosphamide, in combination with glucocorticoids, have been used for remission induction in GPA and MPA. Rituximab has been shown to provide similar benefits to cyclophosphamide for remission induction in a randomized controlled trial (9). Although the currently used cumulative doses of cyclophosphamide are lower than previous regimens and result in less toxicity per treatment course, rituximab is still preferred, since rituximab is considered less toxic than cyclophosphamide. A single course of cyclophosphamide can carry substantial risks such as neutropenia, bladder injury, and the small but present potential for infertility which can be devastating to a young patient. Risks of malignancy and infertility increase when repeated courses of cyclophosphamide are used. Rituximab was also preferred by the Patient Panel, as a generally better-tolerated treatment. Retrospective studies suggest that the 2 remission induction regimens for rituximab used in adults (375 mg/m^2 every week for 4 weeks [US Food and Drug Administration (FDA)–approved dosing schedule] and 1,000 mg on days 1 and 15) are equally efficacious. The choice between these regimens should be guided by the patient's preferences and values.

Cyclophosphamide (dosing provided in Table 1) may be used when rituximab needs to be avoided or when patients have active disease despite receiving rituximab treatment. It remains controversial whether cyclophosphamide should be preferred for certain types of severe disease, such as acute renal failure (e.g., serum creatinine >4.0 mg/dl). Either intravenous (IV) pulse or daily oral cyclophosphamide can be used (10,11). For adults, the decision between these 2 options should be based on patient and physician preferences. In children, IV cyclophosphamide may be preferred to facilitate compliance and limit toxicity. Data regarding the efficacy of combined cyclophosphamide and rituximab therapy for remission induction remain limited (12), and potential toxicity of this combination remains a concern. The combination of rituximab with cyclophosphamide is not widely used in the US, and its efficacy compared to rituximab

Table 2. Recommendations/statements for the management of GPA and MPA*

Recommendation/statement	PICO question informing recommendation and discussion	Level of evidence
Remission induction for active, severe disease		
Recommendation: For patients with active, severe GPA/MPA, we conditionally recommend treatment with rituximab over cyclophosphamide for remission induction.	4, 5, 6	Very low to moderate
Recommendation: In patients with GPA/MPA with active glomerulonephritis, we conditionally recommend *against* the routine addition of plasma exchange to remission induction therapy.	34	Low to high
Recommendation: In patients with active, severe GPA/MPA with alveolar hemorrhage, we conditionally recommend *against* adding plasma exchange to remission induction therapies.	35	Low to high
Ungraded position statement: For patients with active, severe GPA/MPA, either IV pulse GCs or high-dose oral GCs may be prescribed as part of initial therapy.	2	Very low to moderate
Recommendation: In patients with active, severe GPA/MPA, we conditionally recommend a reduced-dose GC regimen over a standard-dose GC regimen for remission induction.	3	Very low to moderate
Remission induction for active, nonsevere disease		
Recommendation: For patients with active, nonsevere GPA, we conditionally recommend initiating treatment with methotrexate over cyclophosphamide or rituximab.	12, 13	Very low to moderate
Recommendation: For patients with active, nonsevere GPA, we conditionally recommend initiating treatment with methotrexate and GCs over GCs alone.	14	Low
Recommendation: For patients with active, nonsevere GPA, we conditionally recommend initiating treatment with methotrexate and GCs over azathioprine and GCs or mycophenolate mofetil and GCs.	8, 9, 10	Low
Recommendation: For patients with active, nonsevere GPA, we conditionally recommend initiating treatment with methotrexate and GCs over trimethoprim/sulfamethoxazole and GCs.	11	Low
Remission maintenance		
Recommendation: For patients with severe GPA/MPA whose disease has entered remission after treatment with cyclophosphamide or rituximab, we conditionally recommend treatment with rituximab over methotrexate or azathioprine for remission maintenance.	15, 16, 17, 18	Very low to moderate
Recommendation: For patients with GPA/MPA who are receiving rituximab for remission maintenance, we conditionally recommend scheduled re-dosing over using ANCA titers or CD19+ B cell counts to guide re-dosing.	24, 25	Very low to low
Recommendation: For patients with severe GPA/MPA whose disease has entered remission after treatment with cyclophosphamide or rituximab, we conditionally recommend treatment with methotrexate or azathioprine over mycophenolate mofetil for remission maintenance.	19	Very low to moderate
Recommendation: For patients with severe GPA/MPA whose disease has entered remission after treatment with cyclophosphamide or rituximab, we conditionally recommend treatment with methotrexate or azathioprine over leflunomide for remission maintenance.	20	Very low to low
Recommendation: For patients with GPA whose disease has entered remission, we conditionally recommend treatment with methotrexate or azathioprine over trimethoprim/sulfamethoxazole for remission maintenance.	21, 22	Very low to low
Recommendation: In patients with GPA whose disease has entered remission, we conditionally recommend *against* adding trimethoprim/sulfamethoxazole to other therapies (e.g., rituximab, azathioprine, methotrexate, etc.) for the purpose of remission maintenance.	23	Low to moderate
Recommendation: For patients with GPA/MPA receiving remission maintenance therapy with rituximab who have hypogammaglobulinemia (e.g., IgG <3 gm/liter) and recurrent severe infections, we conditionally recommend immunoglobulin supplementation.	44	Very low
Ungraded position statement: The duration of non-GC remission maintenance therapy in GPA/MPA should be guided by the patient's clinical condition, preferences, and values.	26	Low to moderate
Ungraded position statement: The duration of GC therapy for GPA/MPA should be guided by the patient's clinical condition, preferences, and values.	27, 33	Low to moderate
Treatment of disease relapse		
Recommendation: For patients with GPA/MPA who have experienced relapse with severe disease manifestations and are not receiving rituximab for remission maintenance, we conditionally recommend treatment with rituximab over cyclophosphamide for remission re-induction.	28	Low
Recommendation: For patients with GPA/MPA who experienced relapse with severe disease manifestations while receiving rituximab for remission maintenance, we conditionally recommend switching from rituximab to cyclophosphamide over receiving additional rituximab for remission re-induction.	29	Very low
Treatment of refractory disease		
Recommendation: For patients with severe GPA/MPA that is refractory to treatment with rituximab or cyclophosphamide for remission induction, we conditionally recommend switching treatment to the other therapy over combining the 2 therapies.	30	Very low
Recommendation: For patients with GPA/MPA that is refractory to remission induction therapy, we conditionally recommend adding IVIG to current therapy.	31	Low to moderate

(Continued)

Table 2. *(Cont'd)*

Recommendation/statement	PICO question informing recommendation and discussion	Level of evidence
Treatment of sinonasal, airway, and mass lesions		
Ungraded position statement: For patients with sinonasal involvement in GPA, nasal rinses and topical nasal therapies (antibiotics, lubricants, and GCs) may be beneficial.	36, 37, 38, 39	Very low to low
Recommendation: For patients with GPA in remission who have nasal septal defects and/or nasal bridge collapse, we conditionally recommend reconstructive surgery, if desired by the patient.	45	Low
Recommendation: For patients with GPA and actively inflamed subglottic and/or endobronchial tissue with stenosis, we conditionally recommend treating with immunosuppressive therapy over surgical dilation with intralesional GC injection alone.	40	Low
Recommendation: For patients with GPA and mass lesions (e.g., orbital pseudotumor or masses of the parotid glands, brain, or lungs), we conditionally recommend treatment with immunosuppressive therapy over surgical removal of the mass lesion with immunosuppressive therapy.	41, 42	Very low to low
Other considerations		
Recommendation: In patients with GPA/MPA, we conditionally recommend *against* dosing immunosuppressive therapy based on ANCA titer results alone.	1	Very low
Recommendation: For patients with GPA who are receiving rituximab or cyclophosphamide, we conditionally recommend prophylaxis to prevent *Pneumocystis jirovecii* pneumonia.	43	Low
Recommendation: For patients with GPA/MPA in remission and stage 5 chronic kidney disease, we conditionally recommend evaluation for renal transplantation.	46	Low
Recommendation: For patients with active GPA/MPA who are unable to receive other immunomodulatory therapy, we conditionally recommend administering IVIG.	32	Low
Ungraded position statement: The optimal duration of anticoagulation is unknown for patients with GPA/MPA who experience venous thrombotic events.	47	Very low

* For the population, intervention, comparator, and outcome (PICO) questions used in the Grading of Recommendations Assessment, Development and Evaluation methodology, as developed for granulomatosis with polyangiitis (GPA) and microscopic polyangiitis (MPA), please refer to Supplementary Appendix 2 (available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24634/abstract). IV = intravenous; GCs = glucocorticoids; ANCA = antineutrophil cytoplasmic antibody; IVIG = IV immunoglobulin.

or cyclophosphamide monotherapy is not established. This combination remains under study (ClinicalTrials.gov identifier: NCT03942887) at this time.

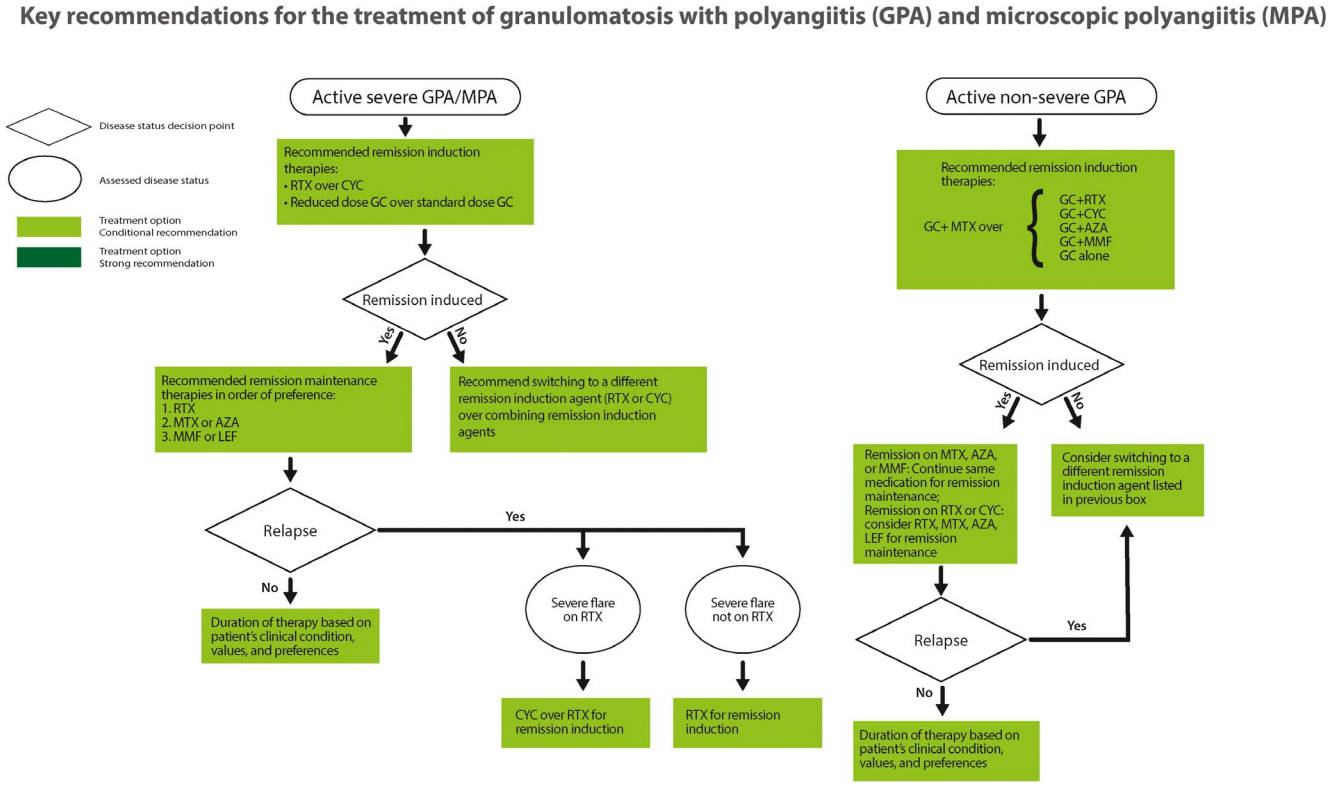
Recommendation: In patients with GPA/MPA with active glomerulonephritis, we conditionally recommend *against* the routine addition of plasma exchange to remission induction therapy.

Plasma exchange should not be initiated in all patients with active glomerulonephritis but can be considered for patients at higher risk of progression to end-stage renal disease (ESRD) who accept a potential increased risk of infection.

This recommendation is supported by data from the 2 largest trials of plasma exchange for the treatment of glomerulonephritis in AAV. The first trial, which required a serum creatinine level of ≥5.8 mg/dl for entry, showed that plasma exchange decreased the risk of ESRD but did not decrease mortality (13,14). In a more recent randomized trial of plasma exchange in AAV, the addition of plasma exchange to conventional remission induction therapy did not improve the composite outcome of ESRD or death; a decrease in the risk of ESRD was observed, but the result was not statistically significant (hazard ratio 0.81 [95% confidence interval (95% CI) 0.57–1.13]) (15).

However, combined data from these 2 trials show that there is probably a decreased risk of ESRD in patients with glomerulonephritis who received plasma exchange, compared to those who did not (hazard ratio 0.72 [95% CI 0.53–0.98]; moderate certainty) (Supplementary Appendix 2, http://onlinelibrary.wiley.com/doi/10.1002/acr.24634/abstract). The benefit was most pronounced in patients with the highest risk of ESRD (118 fewer cases of ESRD per 1,000 cases of active glomerulonephritis [95% CI between 217 and 7 fewer cases]), although no difference in mortality was demonstrated (risk ratio 1.15 [95% CI 0.78–1.70]; moderate certainty). In 4 trials of plasma exchange in AAV, a higher risk of severe infection was observed with plasma exchange (risk ratio 1.19 [95% CI 0.99–1.42]; moderate certainty).

These findings suggest that for patients with a low risk of progression to ESRD, the risk of plasma exchange may outweigh the benefit; however, in patients with a higher risk of progression to ESRD, the decrease in risk could outweigh the increased risk of serious infection with plasma exchange. Therefore, the Voting Panel does not recommend plasma exchange for all patients with active glomerulonephritis but favors consideration of the treatment for patients at a higher risk of progression to ESRD. Factors that could influence whether plasma exchange is initiated include the patient's kidney function upon presentation, rate of loss of kidney function, response to remission induction therapies, and the patient's ability to tolerate serious infections.



Key recommendations for the treatment of granulomatosis with polyangiitis (GPA) and microscopic polyangiitis (MPA)
Disease status decision point
Assessed disease status
Treatment option
Conditional recommendation
Treatment option
Strong recommendation
Active severe GPA/MPA
Recommended remission induction therapies:
• RTX over CYC
• Reduced dose GC over standard dose GC
Remission induced
Yes
No
Recommended remission maintenance therapies in order of preference:
1. RTX
2. MTX or AZA
3. MMF or LEF
Recommend switching to a different remission induction agent (RTX or CYC) over combining remission induction agents
Relapse
Yes
No
Duration of therapy based on patient's clinical condition, values, and preferences
Severe flare on RTX
Severe flare not on RTX
CYC over RTX for remission induction
RTX for remission induction
Active non-severe GPA
Recommended remission induction therapies:
GC+ MTX over
GC+RTX
GC+CYC
GC+AZA
GC+MMF
GC alone
Remission induced
Yes
No
Remission on MTX, AZA, or MMF: Continue same medication for remission maintenance;
Remission on RTX or CYC: consider RTX, MTX, AZA, LEF for remission maintenance
Consider switching to a different remission induction agent listed in previous box
Relapse
Yes
No
Duration of therapy based on patient's clinical condition, values, and preferences

AZA = azathioprine, CYC = cyclophosphamide, GC = glucocorticoids, LEF = leflunomide, MMF = mycophenolate mofetil, MTX = methotrexate, RTX = rituximab

Figure 1. Key recommendations for the treatment of granulomatosis with polyangiitis and microscopic polyangiitis.

Plasma exchange remains advisable in patients with GPA or MPA who also have anti–glomerular basement membrane disease.

Recommendation: In patients with active, severe GPA/MPA with alveolar hemorrhage, we conditionally recommend *against* adding plasma exchange to remission induction therapies.

Two trials evaluated the use of plasma exchange in patients presenting with alveolar hemorrhage, and no differences in mortality or remission rates were observed. Thus, plasma exchange does not have an established benefit for patients with alveolar hemorrhage and is associated with an increased risk of serious infection (see above recommendation). Plasma exchange may be considered for certain patients with active glomerulonephritis or those who are critically ill and whose disease is not responding to recommended remission induction therapies (i.e., plasma exchange as "salvage" or "rescue" therapy).

Plasma exchange remains advisable in patients with GPA or MPA who also have anti–glomerular basement membrane disease.

Ungraded position statement: For patients with active, severe GPA/MPA, either IV pulse glucocorticoids or high-dose oral glucocorticoids may be prescribed as part of initial therapy.

There are no trials comparing the efficacy of IV pulse glucocorticoids to high-dose oral glucocorticoids. Higher doses of glucocorticoids (such as pulse glucocorticoids) are generally administered to patients with organ- or life-threatening disease manifestations but may be associated with an increased risk of infection (16).

Recommendation: For patients with active, severe GPA/MPA, we conditionally recommend a reduced-dose glucocorticoid regimen over a standard-dose glucocorticoid regimen for remission induction.

A recent study demonstrated that a reduced-dose glucocorticoid regimen provided a similar benefit compared to a standard-dose regimen for the composite outcome of ESRD or death, and was associated with a decreased risk of infection (15). Due to the known toxicities associated with long-term glucocorticoid use, minimizing glucocorticoid exposure is critical to improving outcomes. Glucocorticoid dosing may be individualized for each patient. Of note, the reduced-dose regimen started with pulse methylprednisolone (3 daily pulses for maximum total dose of 3 gm) and 1 week of high-dose oral glucocorticoids. The dosing regimens used in this study are described in Supplementary Appendix 3 (http://onlinelibrary.wiley.com/doi/10.1002/acr.24634/abstract).

Remission induction for active, nonsevere disease

Recommendation: For patients with active, nonsevere GPA, we conditionally recommend initiating treatment with methotrexate over cyclophosphamide or rituximab.

Nonsevere GPA is defined as GPA without life- or organ-threatening manifestations (Table 1). Methotrexate, rituximab, and cyclophosphamide are effective at inducing remission in this patient

group (11). However, like severe GPA, nonsevere GPA can be a chronic disease that requires multiple courses of therapy. Thus, the Voting Panel favored using therapies with potentially less toxicity before utilizing therapies with potentially more toxicity. Therefore, methotrexate is preferred due to the greater toxicity of cyclophosphamide. Methotrexate is currently recommended over rituximab because of the larger body of evidence and clinical experience with methotrexate treatment for this patient group; clinical trials are needed to compare their efficacy. Rituximab may be preferred in specific clinical situations, including for patients with hepatic or renal dysfunction, recurrent relapses while receiving methotrexate, or concerns regarding compliance.

Recommendation: For patients with active, nonsevere GPA, we conditionally recommend initiating treatment with methotrexate and glucocorticoids over glucocorticoids alone.

Methotrexate with glucocorticoids is recommended to minimize glucocorticoid exposure and toxicity. Overall, there are few clinical situations in which treatment with glucocorticoid monotherapy may be considered (e.g., arthralgias or inability to tolerate other remission maintenance therapies), and close monitoring is needed if this treatment strategy is used.

Recommendation: For patients with active, nonsevere GPA, we conditionally recommend initiating treatment with methotrexate and glucocorticoids over azathioprine and glucocorticoids or mycophenolate mofetil and glucocorticoids.

The use of methotrexate for remission induction in this patient group is supported by more available data than other treatments (11), but azathioprine and mycophenolate mofetil can be considered. Comparative effectiveness trials are needed to evaluate the efficacy of methotrexate, azathioprine, and mycophenolate mofetil for remission induction in active, nonsevere GPA. Clinical factors may influence the medication selected. For example, methotrexate should be used with caution or avoided in patients with moderate-to-severe renal insufficiency. Azathioprine is the preferred agent for pregnant patients or in patients who cannot tolerate methotrexate or mycophenolate mofetil, while methotrexate or mycophenolate mofetil is indicated in patients with total thiopurine S-methyltransferase deficiency or high-risk *TPMT* and/or *NUDT15* genotypes.

Recommendation: For patients with active, nonsevere GPA, we conditionally recommend initiating treatment with methotrexate and glucocorticoids over trimethoprim/sulfamethoxazole and glucocorticoids.

Methotrexate is considered more effective than trimethoprim/sulfamethoxazole for remission induction, based on previous findings (17). Low-dose trimethoprim/sulfamethoxazole may be administered concurrently with immunosuppressive agents to prevent *Pneumocystis jirovecii* pneumonia (see GPA/MPA recommendation on this topic).

Remission maintenance

Recommendation: For patients with severe GPA/MPA whose disease has entered remission after treatment with cyclophosphamide or rituximab, we conditionally recommend treatment with rituximab over methotrexate or azathioprine for remission maintenance.

Rituximab is associated with a lower relapse rate than azathioprine when used for remission maintenance after remission induction with cyclophosphamide (18). Methotrexate and azathioprine have comparable efficacy rates for remission maintenance (19). Therefore, rituximab is favored over methotrexate or azathioprine. However, more long-term safety data are available for methotrexate and azathioprine, and cost and other factors may limit rituximab use.

Different doses of rituximab have been used for remission maintenance, including IV 500 mg every 6 months (18) (FDA-approved), IV 1,000 mg every 4 months (20), and IV 1,000 mg every 6 months (21). No comparative trials have been conducted. Thus, the optimal dose of rituximab for remission maintenance remains uncertain.

If methotrexate or azathioprine treatment is being considered for remission maintenance, the patient's clinical situation, preferences, and values should guide selection between them, given their comparable efficacy.

Recommendation: For patients with GPA/MPA who are receiving rituximab for remission maintenance, we conditionally recommend scheduled re-dosing over using ANCA titers or CD19+ B cell counts to guide re-dosing.

In one randomized trial, patients who received rituximab for remission maintenance based on changes in CD19+ B cell counts and/or ANCA titers had similar rates of relapse as those receiving rituximab as a scheduled dose. However, this study was limited by the small sample size, and there were wide CIs for the effect size (22). This recommendation is based in part on the experience and expertise of the Voting Panel, which recognized that flares can occur when patients experience CD19+ B cell depletion and/or when test results for ANCA are negative. Thus, CD19+ B cell counts or ANCA titers may not accurately indicate the potential for a patient's disease to flare.

Recommendation: For patients with severe GPA/MPA whose disease has entered remission after treatment with cyclophosphamide or rituximab, we conditionally recommend treatment with methotrexate or azathioprine over mycophenolate mofetil for remission maintenance.

Methotrexate and azathioprine are equally efficacious for remission maintenance (19). Azathioprine is favored over mycophenolate mofetil because the relapse rate with mycophenolate mofetil was higher than with azathioprine when studied with remission maintenance (23). Mycophenolate mofetil may still be considered for those unable to tolerate or with contraindications to methotrexate, azathioprine, or rituximab.

Recommendation: For patients with severe GPA/MPA whose disease has entered remission after treatment with cyclophosphamide or rituximab, we conditionally recommend treatment with methotrexate or azathioprine over leflunomide for remission maintenance.

Methotrexate or azathioprine treatment is recommended over leflunomide due to the data supporting and clinical experience using methotrexate and azathioprine for remission maintenance. The data and clinical experience with leflunomide are more limited. In one clinical trial comparing leflunomide to methotrexate treatment, leflunomide treatment demonstrated a decreased rate of relapse but a higher rate of drug withdrawal (24). The trial used a leflunomide dose of 30 mg/day, which may have contributed to toxicity.

Recommendation: For patients with GPA whose disease has entered remission, we conditionally recommend treatment with methotrexate or azathioprine over trimethoprim/sulfamethoxazole for remission maintenance.

The Voting Panel strongly favored the use of methotrexate or azathioprine over trimethoprim/sulfamethoxazole, but this recommendation is conditional due to the lack of sufficient high-quality evidence comparing the 2 treatments.

Recommendation: In patients with GPA whose disease has entered remission, we conditionally recommend *against* adding trimethoprim/sulfamethoxazole to other therapies (e.g., rituximab, azathioprine, methotrexate, etc.) for the purpose of remission maintenance.

Trimethoprim/sulfamethoxazole may have benefit for patients with sinonasal involvement (25), but its use potentially increases toxicity (e.g., severe hypersensitivity reactions) and medication burden. Trimethoprim/sulfamethoxazole may still be indicated for prophylaxis against *P jirovecii* pneumonia (see GPA/MPA recommendation on this topic). There is a potential drug interaction between methotrexate and trimethoprim/sulfamethoxazole when trimethoprim/sulfamethoxazole is dosed at 800 mg/160 mg twice a day. The trimethoprim/sulfamethoxazole dose used for *Pneumocystis* prophylaxis is generally tolerated, but its use should be monitored when used in conjunction with methotrexate.

Recommendation: For patients with GPA/MPA receiving remission maintenance therapy with rituximab who have hypogammaglobulinemia (e.g., IgG <3 gm/liter) and recurrent severe infections, we conditionally recommend immunoglobulin supplementation.

Immunoglobulin supplementation at replacement doses (e.g., 400–800 mg/kg/month) should be considered if a patient has hypogammaglobulinemia and is experiencing recurrent infections. Immunoglobulin supplementation can also be considered for patients with hypogammaglobulinemia without recurrent infections but with impaired vaccine responses (26). These considerations should be made in collaboration with an allergist/immunologist.

Ungraded position statement: The duration of nonglucocorticoid remission maintenance therapy in GPA/MPA should be guided by the patient's clinical condition, preferences, and values.

The optimal duration of remission maintenance therapy is not well established. Although clinical trials have typically administered remission maintenance therapy for ≥18 months, patients may benefit from continuing remission maintenance therapy for a longer duration (27). The Patient Panel favored remission maintenance therapy for ≥18 months and potentially longer depending on patient-specific factors. Factors to be considered include previous relapse history, extent of organ involvement, and disease characteristics such as ANCA status (with PR3-ANCA–positive patients more likely to experience disease relapse [28]).

Ungraded position statement: The duration of glucocorticoid therapy for GPA/MPA should be guided by the patient's clinical condition, preferences, and values.

The optimal duration of glucocorticoid therapy for GPA/MPA is not well established. The immunosuppressive effects of glucocorticoids contributing to disease control should be balanced with the toxicities associated with its use. Overall, patients expressed a desire to minimize the glucocorticoid dose as much as possible but recognized that some patients may require low-dose glucocorticoids long-term to maintain disease quiescence. Screening for toxicities of glucocorticoid use (e.g., bone mineral density testing for osteoporosis) should be conducted.

Treatment of disease relapse

Recommendation: For patients with GPA/MPA who have experienced relapse with severe disease manifestations and are not receiving rituximab for remission maintenance, we conditionally recommend treatment with rituximab over cyclophosphamide for remission re-induction.

Rituximab is more effective than oral cyclophosphamide for re-induction of remission among patients who previously received cyclophosphamide and then experienced relapse, based on subgroup analysis of a randomized controlled trial (9). In addition, the cumulative toxicity of cyclophosphamide raises concerns over repeated use of this agent.

Recommendation: For patients with GPA/MPA who experienced relapse with severe disease manifestations while receiving rituximab for remission maintenance, we conditionally recommend switching from rituximab to cyclophosphamide over receiving additional rituximab for remission re-induction.

Multiple factors can influence whether rituximab or cyclophosphamide treatment (IV or oral) is used, such as time since last rituximab infusion and cumulative cyclophosphamide dose. Cyclophosphamide is recommended if the patient recently received rituximab, while a remission induction dose of rituximab may be

effective if an extended period has passed since the last rituximab infusion. As is standard for remission induction, these agents should be used in conjunction with glucocorticoids.

Treatment of refractory disease

Recommendation: For patients with severe GPA/MPA that is refractory to treatment with rituximab or cyclophosphamide for remission induction, we conditionally recommend switching treatment to the other therapy over combining the 2 therapies.

Disease refractory to remission induction therapy is rare, and there are limited data to guide treatment recommendations. Practitioners should evaluate whether other conditions such as infection could be mimicking vasculitis. However, if a patient's disease is refractory to one remission induction therapy, it is important to change the remission induction strategy. We recommend switching to the other remission induction agent prior to using combination therapy.

Recommendation: For patients with GPA/MPA that is refractory to remission induction therapy, we conditionally recommend adding IV immunoglobulin (IVIG) to current therapy.

IVIG should not be used routinely to treat GPA/MPA but can be considered at certain treatment doses (e.g., 2 gm/kg) as adjunctive therapy for short-term control, while waiting for remission induction therapy (i.e., rituximab or cyclophosphamide) to become effective (see above recommendation) (29).

Treatment of sinonasal, airway, and mass lesions

Ungraded position statement: For patients with sinonasal involvement in GPA, nasal rinses and topical nasal therapies (antibiotics, lubricants, and glucocorticoids) may be beneficial.

We suggest collaborating with an otolaryngologist with expertise in treating GPA to determine whether these interventions should be used.

Recommendation: For patients with GPA in remission who have nasal septal defects and/or nasal bridge collapse, we conditionally recommend reconstructive surgery, if desired by the patient.

To optimize surgical outcomes, reconstructive surgery should be performed, after a period of sustained remission, by an otolaryngologist with expertise in treating GPA (30,31).

Recommendation: For patients with GPA and actively inflamed subglottic and/or endobronchial tissue with stenosis, we conditionally recommend treating with immunosuppressive therapy over surgical dilation with intralesional glucocorticoid injection alone.

Subglottic or endobronchial stenoses should be managed by an otolaryngologist or pulmonologist, respectively, with expertise in management of these lesions. Immunosuppressive therapy is recommended for initial treatment of active inflammatory stenoses and usually comprises glucocorticoids and other agents (32); the degree of immunosuppressive therapy utilized may be based on the severity of other disease manifestations. Surgical dilation with intralesional glucocorticoid injection may be more appropriate for stenoses that are longstanding, fibrotic, or unresponsive to immunosuppression (32–34). Surgical dilation with intralesional glucocorticoid injection concurrent with medical treatment may also be considered as initial therapy for stenoses that require immediate intervention (e.g., critical narrowing).

Recommendation: For patients with GPA and mass lesions (e.g., orbital pseudotumor or masses of the parotid glands, brain, or lungs), we conditionally recommend treatment with immunosuppressive therapy over surgical removal of the mass lesion with immunosuppressive therapy.

Immunosuppressive therapy (with remission induction followed by remission maintenance) is almost always the initial treatment of choice for mass lesions (35,36). While these lesions tend to respond primarily to glucocorticoids, other agents are also usually used in hopes of having a glucocorticoid-sparing effect. Debulking surgery may be considered if there is an urgent need for decompression, such as acute visual loss due to optic nerve compression, or other life- or organ-threatening compression.

Other considerations

Recommendation: In patients with GPA/MPA, we conditionally recommend *against* dosing immunosuppressive therapy based on ANCA titer results alone.

Increases in ANCA titers/levels are only modestly informative as an indicator of disease activity (37) and are not reliable predictors of disease flares for individual patients. Increasing immunosuppressive therapy based on changes in ANCA titers/levels alone can result in unnecessary immunosuppression resulting in adverse events. Persistence of ANCA positivity does not necessarily indicate that continued immunosuppressive therapy is required. Instead, treatment decisions should be based on a patient's clinical symptoms in conjunction with diagnostic studies (e.g., laboratory, imaging, and biopsy findings).

Recommendation: For patients with GPA/MPA who are receiving rituximab or cyclophosphamide, we conditionally recommend prophylaxis to prevent *P jirovecii* pneumonia.

Prophylaxis to prevent *P jirovecii* pneumonia is routinely used with cyclophosphamide treatment (38). The prescribing information for rituximab recommends prophylaxis for *P jirovecii* pneumonia for ≥6 months after the last rituximab dose for patients with GPA or MPA. While many on the Voting Panel felt strongly that patients with GPA/MPA receiving cyclophosphamide or rituximab should receive prophylaxis against *P jirovecii* pneumonia, this recommendation is conditional given the lack of moderate-

Table 3. Recommendations/statements for the management of EGPA*

Recommendation/statement	PICO question informing recommendation and discussion	Level of evidence
Remission induction for active, severe disease		
Ungraded position statement: For patients with active, severe EGPA, either IV pulse GCs or high-dose oral GCs may be prescribed as initial therapy.	3	Very low
Ungraded position statement: For patients with active, severe EGPA, either cyclophosphamide or rituximab may be prescribed for remission induction.	4	Very low
Recommendation: For patients with active, severe EGPA, we conditionally recommend treatment with cyclophosphamide or rituximab over mepolizumab for remission induction.	6, 7	Low
Remission induction for active, nonsevere disease		
Recommendation: For patients with active, nonsevere EGPA, we conditionally recommend initiating treatment with mepolizumab and GCs over methotrexate, azathioprine, or mycophenolate mofetil and GCs.	8, 9, 10, 13	Very low to low
Recommendation: For patients with active, nonsevere EGPA, we conditionally recommend initiating treatment with methotrexate, azathioprine, or mycophenolate mofetil and GCs over GCs alone.	14	Low
Recommendation: For patients with active, nonsevere EGPA, we conditionally recommend initiating treatment with methotrexate, azathioprine, or mycophenolate mofetil and GCs over cyclophosphamide or rituximab and GCs.	11, 12	Very low to low
Remission maintenance		
Recommendation: For patients with severe EGPA whose disease has entered remission with cyclophosphamide therapy, we conditionally recommend treatment with methotrexate, azathioprine, or mycophenolate mofetil over rituximab for remission maintenance.	15, 16, 17,18	Very low
Recommendation: For patients with severe EGPA whose disease has entered remission, we conditionally recommend treatment with methotrexate, azathioprine, or mycophenolate mofetil over mepolizumab for remission maintenance.	20	Very low
Ungraded position statement: The duration of GC therapy in EGPA should be guided by the patient's clinical condition, values, and preferences.	21, 22, 23, 29, 30	Very low to low
Treatment of relapse		
Recommendation: For patients with EGPA who have experienced relapse with severe disease manifestations after prior successful remission induction with cyclophosphamide, we conditionally recommend treatment with rituximab over cyclophosphamide for remission re-induction.	25	Very low
Recommendation: For patients with EGPA who have experienced relapse with severe disease manifestations after prior successful remission induction with rituximab, we conditionally recommend treatment with rituximab over switching to cyclophosphamide for remission re-induction.	25	Very low
Recommendation: For patients with EGPA who have experienced relapse with nonsevere disease manifestations (asthma and/or sinonasal disease) while receiving methotrexate, azathioprine, or mycophenolate mofetil, we conditionally recommend adding mepolizumab over switching to another agent.	26	Very low
Recommendation: For patients with EGPA who have experienced relapse with nonsevere disease manifestations (asthma and/or sinonasal disease) while receiving low-dose GCs and no other therapy, we conditionally recommend adding mepolizumab over adding methotrexate, azathioprine, or mycophenolate mofetil.	28	Very low
Recommendation: For patients with EGPA and high serum IgE levels who have experienced relapse with nonsevere disease manifestations (asthma and/or sinonasal disease) while receiving methotrexate, azathioprine, or mycophenolate mofetil, we conditionally recommend adding mepolizumab over adding omalizumab.	27	Very low
Other considerations		
Recommendation: For patients with newly diagnosed EGPA receiving leukotriene inhibitors, we conditionally recommend continuing leukotriene inhibitors over discontinuing them.	33	Very low
Ungraded position statement: Use of leukotriene inhibitors is not contraindicated for patients with EGPA with active asthma and/or sinonasal disease.	34	Very low
Recommendation: For patients with EGPA, we conditionally recommend obtaining an echocardiogram at the time of diagnosis.	2	Very low
Recommendation: For patients with EGPA, we conditionally recommend using the Five-Factor Score to guide therapy.	1	Very low
Ungraded position statement: In patients with sinonasal involvement in EGPA, treatment with nasal rinses and topical therapies (e.g., antibiotics, lubricants, and GCs) may be considered.	31	Very low
Recommendation: For patients with EGPA who are receiving cyclophosphamide or rituximab, we conditionally recommend prescribing medications for prophylaxis to prevent *Pneumocystis jirovecii* pneumonia.	32	Low

* For the population, intervention, comparator, and outcome (PICO) questions used in the Grading of Recommendations Assessment, Development and Evaluation methodology, as developed for eosinophilic granulomatosis with polyangiitis (EGPA), please refer to Supplementary Appendix 2 (available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24634/abstract). IV = intravenous; GCs = glucocorticoids.

or high-quality evidence directly addressing this question and the potential toxicity of the medications used for prophylaxis. Prophylaxis against *P jirovecii* pneumonia should also be considered for patients receiving moderate-dose glucocorticoids (e.g., >20 mg/day) or higher in combination with methotrexate, azathioprine, or mycophenolate mofetil (38). Prophylaxis

is less commonly used in younger children receiving rituximab but should be considered.

Recommendation: For patients with GPA/MPA in remission and stage 5 chronic kidney disease, we conditionally recommend evaluation for renal transplantation.

Outcomes of kidney transplantation in patients with AAV are similar to those in patients receiving transplants for other reasons, with disease relapses in the transplanted kidney being rare (39,40). GPA and MPA in remission should not be considered a contraindication to kidney transplantation, but these patients should be monitored for disease relapse after transplantation.

Recommendation: For patients with active GPA/MPA who are unable to receive other immunomodulatory therapy, we conditionally recommend administering IVIG.

IVIG should not be used routinely to treat GPA/MPA (see above recommendation). However, in the rare instances in which patients with active disease may not be able to receive conventional immunosuppressive therapy (e.g., sepsis or pregnancy), IVIG can be used as a short-term intervention until conventional remission induction therapies can be used (29).

Ungraded position statement: The optimal duration of anticoagulation is unknown for patients with GPA/MPA who experience venous thrombotic events.

AAV is associated with an increased risk of venous thrombotic events, including both deep vein thromboses and pulmonary emboli (41,42). Venous thromboembolic events that occur in a patient with active disease and no other risk factors can be considered a provoked event with a transient risk factor (assuming subsequent disease control). Thus, short-term instead of lifelong anticoagulation may be considered.

Recommendations and ungraded position statements for EGPA

EGPA is characterized by diverse features, including asthma/allergic rhinitis, peripheral and tissue eosinophilia, and vasculitis. As these clinical features can potentially have differing responses to treatment, the management approach is typically based on a patient's disease features and severity. The recommendations presented here focus primarily on the use of immunosuppressive medications to treat the vasculitic manifestations of EGPA. However, asthma and allergic manifestations are a significant component of EGPA, and measures directed toward these, including inhaled therapies and allergen avoidance, play an important role in management. Collaboration between rheumatologists, asthma/allergy specialists, and specialists in other medical disciplines can enhance the care of patients with EGPA.

In contrast to GPA/MPA, there have been very few randomized controlled trials conducted to date in EGPA. These recommendations and ungraded position statements therefore reflect reliance on lower-quality (i.e., indirect) evidence, including expert opinion.

Table 1 presents the definitions of selected terms used in the recommendations and ungraded position statements, including the definition of severe and nonsevere disease and the dosing regimens of medications used for remission induction and maintenance. Table 3 presents the recommendations and ungraded position statements with their supporting PICO questions and levels of evidence. Figure 2 presents key recommendations for the treatment of EGPA.

Remission induction for active, severe disease

Ungraded position statement: For patients with active, severe EGPA, either IV pulse glucocorticoids or high-dose oral glucocorticoids may be prescribed as initial therapy.

There are no data to support favoring either IV pulse or high-dose oral glucocorticoids over the other option in active, severe EGPA. Choosing an approach should be influenced by individual patient factors. In either instance, glucocorticoids should be combined with a nonglucocorticoid immunosuppressive agent such as cyclophosphamide or rituximab (see ungraded position statement below).

Ungraded position statement: For patients with active, severe EGPA, either cyclophosphamide or rituximab may be prescribed for remission induction.

Cyclophosphamide has been more commonly used for remission induction in patients with active, severe EGPA, given the experience with cyclophosphamide in other forms of vasculitis (43). Increasing experience with rituximab in GPA/MPA has also led to more patients with EGPA being treated with rituximab, and case series suggest that rituximab may also have efficacy for active, severe disease (44). Given that the comparative effectiveness of cyclophosphamide and rituximab for EGPA is unknown, the Voting Panel felt that both cyclophosphamide and rituximab could be considered for remission induction in active, severe EGPA. Cyclophosphamide would be preferred for patients with active cardiac involvement given the increased experience with cyclophosphamide, as cardiomyopathy has been found to be the main independent predictor of death in EGPA (25,26). Cyclophosphamide can also be considered for patients who are ANCA-negative and have severe neurologic or gastrointestinal manifestations. Rituximab may be considered for patients with positive ANCA results, active glomerulonephritis, prior cyclophosphamide treatment, or those at risk of gonadal toxicity from cyclophosphamide.

Recommendation: For patients with active, severe EGPA, we conditionally recommend treatment with cyclophosphamide or rituximab over mepolizumab for remission induction.

The efficacy of mepolizumab in severe EGPA has not been established, as patients with active, severe disease were excluded

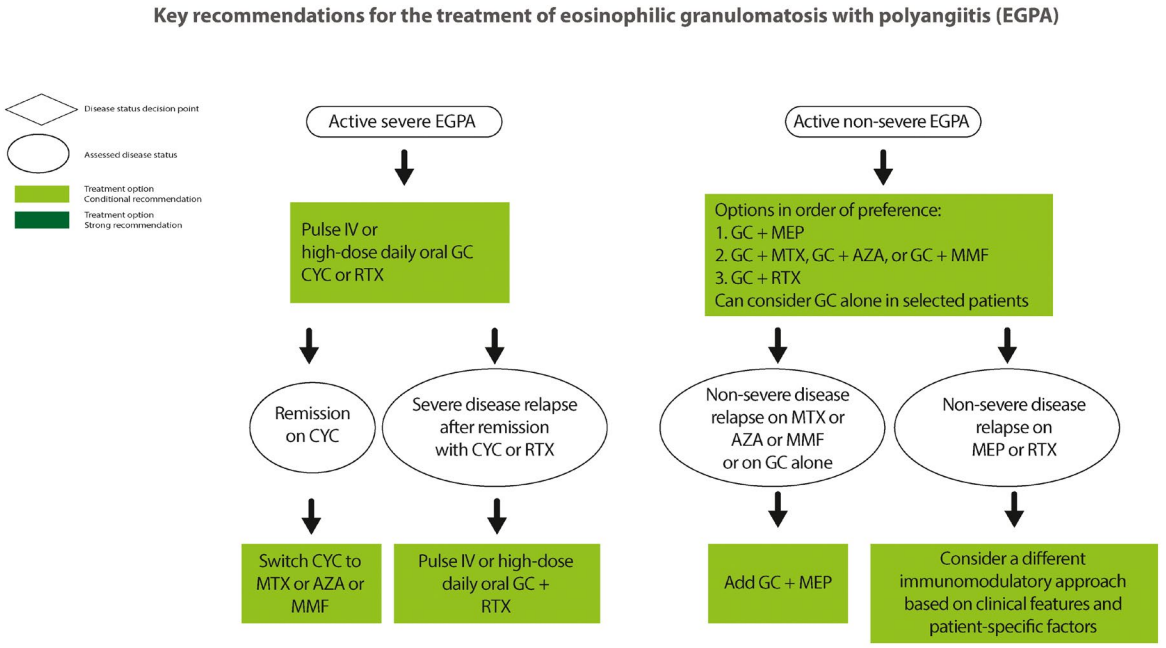


Figure 2. Key recommendations for the treatment of eosinophilic granulomatosis with polyangiitis.

from the randomized trial (45). Rituximab or cyclophosphamide is recommended over mepolizumab in this setting.

Remission induction for active, nonsevere disease

Recommendation: For patients with active, nonsevere EGPA, we conditionally recommend initiating treatment with mepolizumab and glucocorticoids over methotrexate, azathioprine, or mycophenolate mofetil and glucocorticoids.

A range of immunosuppressive agents may be considered in the treatment of active, nonsevere EGPA, all of which are used with glucocorticoids. The clinical profile of nonsevere EGPA includes predominantly asthma, sinus disease, and nonsevere vasculitis. While there is significant clinical experience with methotrexate, azathioprine, and mycophenolate mofetil, there are limited data regarding their efficacy, and these treatments have not been assessed in randomized clinical trials. The GRADE methodology used in the guideline development process weights clinical trials more heavily than observational studies. Thus, mepolizumab is recommended as the first choice, because it has been found to be efficacious for nonsevere EGPA in a randomized trial (45). All patients in this trial had relapsing or refractory disease, with 55% receiving an additional nonglucocorticoid immunosuppressive agent at the time of enrollment. A large proportion of patients in this trial had asthmatic and eosinophilic features, for which mepolizumab has also been found to be effective in non-EGPA disease settings. Although patients with nonsevere vasculitic manifestations were represented in this trial, questions remain about the effectiveness of mepolizumab for all aspects of nonsevere vasculitis. Individual factors, including disease manifestations, may impact the decision to use mepolizumab, in which case methotrexate, azathioprine, or mycophenolate mofetil may be used instead. There are insufficient data to favor one of these medications (methotrexate, azathioprine, or mycophenolate mofetil) over the others; therefore, the choice should be influenced by individual patient factors.

Recommendation: For patients with active, nonsevere EGPA, we conditionally recommend initiating treatment with methotrexate, azathioprine, or mycophenolate mofetil and glucocorticoids over glucocorticoids alone.

Patients should be treated with adjunctive methotrexate, azathioprine, or mycophenolate mofetil rather than glucocorticoids alone in order to minimize glucocorticoid toxicity. One randomized trial that combined patients with EGPA, MPA, and polyarteritis nodosa without poor prognosis factors showed that the addition of azathioprine did not provide benefit beyond glucocorticoids alone (46). Particularly for patients with asthma, this may impact the decision to use methotrexate, azathioprine, or mycophenolate mofetil concurrently with glucocorticoids and could lead to consideration of mepolizumab. Glucocorticoid monotherapy may be appropriate for mild asthma, allergic symptoms, use during pregnancy, or other individual patient situations.

Recommendation: For patients with active, nonsevere EGPA, we conditionally recommend initiating treatment with methotrexate, azathioprine, or mycophenolate mofetil and glucocorticoids over cyclophosphamide or rituximab and glucocorticoids.

While the comparative efficacy of methotrexate, azathioprine, mycophenolate mofetil, and rituximab is not well established, the use of methotrexate, azathioprine, or mycophenolate mofetil is favored, based on more experience with these agents in EGPA compared to rituximab. However, rituximab may be considered if other agents are not effective in controlling active, nonsevere disease, or if the patient has nonsevere vasculitis (which in some series included mononeuritis multiplex) and is positive for ANCA. Cyclophosphamide should be avoided when treating active, nonsevere disease due to its toxicity and is the least preferred option in this setting.

Remission maintenance

Recommendation: For patients with severe EGPA whose disease has entered remission with cyclophosphamide therapy, we conditionally recommend treatment with methotrexate, azathioprine, or mycophenolate mofetil over rituximab for remission maintenance.

Typically, a maintenance agent would be used after remission induction in severe EGPA to reduce toxicity and the risk of disease relapse (47), although monophasic disease can occur (48). Azathioprine has been commonly used in published EGPA series (46), but the lack of comparative evidence between methotrexate, azathioprine, and mycophenolate mofetil in EGPA precludes recommending one agent over another.

Use of methotrexate, azathioprine, or mycophenolate mofetil is recommended over rituximab, because there has been less experience with the use of rituximab for remission maintenance in EGPA. Rituximab could be considered if remission were induced with rituximab or if there are contraindications to other choices.

Recommendation: For patients with severe EGPA whose disease has entered remission, we conditionally recommend treatment with methotrexate, azathioprine, or mycophenolate mofetil over mepolizumab for remission maintenance.

While there are limited data informing the use of remission maintenance therapy in EGPA, remission induction therapies (e.g., cyclophosphamide) should not be indefinitely continued given the potential toxicity. Thus, methotrexate, azathioprine, or mycophenolate mofetil can be considered for remission maintenance based on experience in GPA/MPA, expert opinion, and results from small studies (49). The primary experience with mepolizumab is in refractory nonsevere disease, and thus it is difficult to extrapolate its efficacy as a remission maintenance agent for severe disease.

Ungraded position statement: The duration of glucocorticoid therapy in EGPA should be guided by the patient's clinical condition, values, and preferences.

There is insufficient published evidence to support a specific duration of glucocorticoid treatment, and thus, the length of glucocorticoid therapy should be determined based on each patient's clinical circumstances. Many patients with EGPA require some treatment with glucocorticoids, generally at a low dose, to maintain control of asthma and allergy symptoms. The minimum effective dose should be prescribed to minimize glucocorticoid toxicity.

Treatment of disease relapse

Recommendation: For patients with EGPA who have experienced relapse with severe disease manifestations after prior successful remission induction with cyclophosphamide, we conditionally recommend treatment with rituximab over cyclophosphamide for remission re-induction.

Rituximab is favored based on the general desire to avoid re-treatment with cyclophosphamide if possible and on the findings of an observational study of rituximab in relapsing or refractory EGPA (50). Cyclophosphamide may be considered in instances of recurrent cardiac involvement, since cardiac involvement is an independent predictor of death and is associated with ANCA-negative disease, as discussed in the ungraded position statement about remission induction in active, severe disease.

Recommendation: For patients with EGPA who have experienced relapse with severe disease manifestations after prior successful remission induction with rituximab, we conditionally recommend treatment with rituximab over switching to cyclophosphamide for remission re-induction.

Re-induction of remission with rituximab is favored over cyclophosphamide treatment to minimize toxicity. However, the duration of remission prior to the onset of relapse should be examined. Cyclophosphamide should be considered if a severe relapse occurred quickly after rituximab treatment, or if cardiac involvement is present (see ungraded position statement and recommendation on this topic).

Recommendation: For patients with EGPA who have experienced relapse with nonsevere disease manifestations (asthma and/or sinonasal disease) while receiving methotrexate, azathioprine, or mycophenolate mofetil, we conditionally recommend adding mepolizumab over switching to another agent.

For patients with EGPA with active asthma, inhaled therapies should be maximized prior to increasing systemic immunosuppressive therapy. Although no direct comparative

data are available, mepolizumab was found to be efficacious in a randomized trial in patients specifically described in this recommendation: those with relapsing nonsevere EGPA who are receiving immunosuppressive therapy (45). It has also been independently proven to be effective in eosinophilic asthma (51). Based on this evidence, mepolizumab is recommended to treat nonsevere relapsing disease in patients receiving methotrexate, azathioprine, or mycophenolate mofetil rather than switching to an alternative agent of that group.

Recommendation: For patients with EGPA who have experienced relapse with nonsevere disease manifestations (asthma and/or sinonasal disease) while receiving low-dose glucocorticoids and no other therapy, we conditionally recommend adding mepolizumab over adding methotrexate, azathioprine, or mycophenolate mofetil.

Similar to the discussion about the above recommendation, use of inhaled agents should be optimized in patients experiencing disease relapse with asthma and/or sinonasal disease. For patients with nonsevere relapsing EGPA who are receiving glucocorticoid monotherapy, starting mepolizumab would be preferred over adding methotrexate, azathioprine, or mycophenolate mofetil, given the treatment's proven efficacy in this population in a randomized trial (45).

Recommendation: For patients with EGPA and high serum IgE levels who have experienced relapse with nonsevere disease manifestations (asthma and/or sinonasal disease) while receiving methotrexate, azathioprine, or mycophenolate mofetil, we conditionally recommend adding mepolizumab over adding omalizumab.

The published evidence on omalizumab, an anti-IgE antibody, in EGPA has been limited. Therefore, even for a patient with high serum IgE levels, mepolizumab is the preferred choice based on evidence from the randomized controlled trial (45).

Other considerations

Recommendation: For patients with newly diagnosed EGPA receiving leukotriene inhibitors, we conditionally recommend continuing leukotriene inhibitors over discontinuing them.

Following the introduction of leukotriene inhibitors, concerns were raised about a link with the development of EGPA. In subsequent retrospective studies, it was not concluded that there is a causal relationship between leukotriene inhibitors and EGPA (52). Therefore, patients with newly diagnosed EGPA should have the option to continue a leukotriene inhibitor if it is beneficial in the management of their asthma or sinonasal disease.

Ungraded position statement: Use of leukotriene inhibitors is not contraindicated for patients with EGPA with active asthma and/or sinonasal disease.

Leukotriene inhibitors carry therapeutic indications for asthma and allergic rhinitis. As no clear causal association with EGPA has been demonstrated, a leukotriene inhibitor can be added to help manage asthma and sinonasal disease. However, leukotriene inhibitors are one of many options and are not the only choice in this setting. Leukotriene inhibitors should not be used to treat manifestations aside from asthma and sinonasal disease.

Recommendation: For patients with EGPA, we conditionally recommend obtaining an echocardiogram at the time of diagnosis.

Cardiac involvement is the major cause of disease-related mortality in EGPA (48). Echocardiography has minimal risk and can identify cardiac involvement, which, if present, can impact treatment decisions. Not identifying cardiac involvement could negatively impact patient outcomes. Thus, we recommend obtaining an echocardiogram for all patients with newly diagnosed EGPA, even in the absence of cardiac symptoms.

Recommendation: For patients with EGPA, we conditionally recommend using the Five-Factor Score to guide therapy.

The Five-Factor Score (FFS), first published in 1996 (53), was based on a cohort of 342 patients with either polyarteritis nodosa, as it was then defined, or EGPA. These 5 factors include proteinuria >1 gm/day, renal insufficiency with serum creatinine >1.58 mg/dl, gastrointestinal tract involvement, cardiomyopathy, and central nervous system involvement. The FFS is primarily a prognostic tool for which higher scores have been associated with a worse outcome (53). It has been used to guide treatment (43), but its applicability to newer therapies is unknown. The FFS was revisited in 2011 in a population of 1,108 patients with GPA, MPA, EGPA, or PAN (54). The 2011 version included ear, nose, and throat parameters and age >65 years. The 1996 FFS remains more commonly used and may be helpful in identifying organ-specific parameters associated with severe disease and in guiding treatment. Although the definitions of severe and nonsevere EGPA used in the present guideline were not based on the FFS, the tool was found to be useful to clinicians for making treatment decisions. The components of the FFS can serve as markers of severe disease that warrant more aggressive treatment.

Ungraded position statement: In patients with sinonasal involvement in EGPA, treatment with nasal rinses and topical therapies (e.g., antibiotics, lubricants, and glucocorticoids) may be considered.

Allergic rhinitis and sinonasal disease are frequent clinical features of EGPA. Although the efficacy of nasal rinses and topical

therapies in EGPA is not well established, some patients may benefit. Where possible, consultation with an otolaryngologist with expertise in treating AAV should be obtained to guide the use and choice of these agents. These interventions can continue to be beneficial even when symptoms have improved or resolved.

Recommendation: For patients with EGPA who are receiving cyclophosphamide or rituximab, we conditionally recommend prescribing medications for prophylaxis to prevent *P jirovecii* pneumonia.

Prophylaxis to prevent *P jirovecii* pneumonia is discussed above in the GPA/MPA recommendations. The same considerations regarding prophylaxis to prevent this condition in patients with GPA/MPA apply to those with EGPA.

DISCUSSION

In this guideline, we present the first ACR/Vasculitis Foundation recommendations for the management of GPA, MPA, and EGPA. Although these recommendations provide a general guide for disease management, the patient's clinical condition, preferences, and values should influence their treatment. Overall, these recommendations reflect the evolving management of these diseases, including the new roles for biologic therapies and aggressive strategies to minimize glucocorticoid toxicity. The recommendations for GPA and MPA are supported by a greater number of randomized trials than are currently available in EGPA. All of the recommendations made for these 3 diseases are conditional, which indicates that there are settings in which the evidence is not strong or an alternative is a reasonable consideration. These recommendations should not be used by any agency to restrict access to therapy or require that certain therapies be utilized prior to other therapies.

The physicians on the Voting Panel were primarily rheumatologists, because the recommendations were being developed for rheumatologists in the US. Since AAVs are multisystem diseases, patients with AAVs often receive care from other medical subspecialists (e.g., nephrologists, pulmonologists, and/or otolaryngologists). While the recommendations presented in this guideline are driven by the published data, other medical subspecialists may favor a different management strategy. We encourage rheumatologists to discuss treatment plans and coordinate care with other subspecialists as needed.

Recently, a clinical trial of avacopan in patients with GPA and MPA was published (55). This guideline development effort did not include consideration of avacopan, since the guidelines consider therapies that are approved by the FDA for use for any indication at the time of the last literature search. Therapies approved by the FDA after that date will be considered for inclusion in future updates to this guideline.

This guideline highlights gaps in our knowledge for the treatment of AAV. Most glaring is the lack of biomarker assessments or other noninvasive diagnostic testing with minimal toxicity that can accurately assess disease activity and predict outcomes. In addition, while we have evidence from randomized clinical trials to support recommendations regarding initial remission induction and maintenance therapy, critical questions remain unanswered, such as the optimal duration of therapy.

These gaps in knowledge reinforce the need for ongoing research in these diseases. Specific areas to investigate include the following: 1) biomarker studies to identify more specific, reliable indicators of disease activity that can guide treatment decisions; 2) trials to clarify how best to use the currently available medications (e.g., dosing, duration, effective combinations, and in which population to use which drugs); 3) trials to identify novel, targeted, and/or glucocorticoid-sparing agents with minimal toxicity; and 4) long-term studies to understand the course of disease and the safety of current therapies.

We hope significant progress will be made in these areas such that future recommendations provide a more tailored approach to disease management, minimize treatment toxicity, and prevent organ damage in these patients.

ACKNOWLEDGMENTS

We thank Anne M. Ferris, MBBS, Ora Gewurz-Singer, MD, Rula Hajj-Ali, MD, Eric Matteson, MD, MPH, Robert F. Spiera, MD, Linda Wagner-Weiner, MD, MS, and Kenneth J. Warrington, MD, for serving on the Expert Panel. We thank Antoine G. Sreih, MD, and Gary S. Hoffman, MD, MS, for their contributions during the early phases of this project as members of the Core Team. Dr. Hoffman's participation ended July 2018 due to personal reasons. Dr. Sreih's involvement ended in December 2018 when he became primarily employed by industry, which precluded his continued participation in this project. We thank Joyce Kullman (Vasculitis Foundation) for her assistance with recruitment for the Patient Panel. We thank the patients who (along with authors Kathy A. Full and Omar I. Vitobaldi) participated in the Patient Panel meeting: Jane Ascroft, Scott A. Brunton, Dedra DeMarco, Thomas Fitzpatrick, Jenn Gordon, Maria S. Mckay, Sandra Nye, Stephanie Sakson, and Ben Wilson. We thank Robin Arnold, Catherine E. Najem, MD, MSCE, and Amit Aakash Shah, MD, MPH, for their assistance with the literature review. We thank the ACR staff, including Ms Regina Parker, for assistance in organizing the face-to-face meeting and coordinating the administrative aspects of the project, and Ms Robin Lane for assistance in manuscript preparation. We thank Ms Janet Waters for help in developing the literature search strategy and performing the initial literature search, and Ms Janet Joyce for performing the update searches.

AUTHOR CONTRIBUTIONS

All authors were involved in drafting the article or revising it critically for important intellectual content, and all authors approved the final version to be published. Drs. Chung and Langford had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Study conception and design. Chung, Langford, Maz, Abril, Gorelik, Guyatt, Archer, Full, Grayson, Merkel, Seo, Stone, Sule, Sundel, Vitobaldi, Turner, Mustafa.

Acquisition of data. Chung, Langford, Maz, Abril, Gorelik, Full, Imundo, Kim, Merkel, Stone, Vitobaldi, Byram, Dua, Husainat, James, Kalot, Lin, Springer, Turgunbaev, Villa-Forte, Turner, Mustafa.

Analysis and interpretation of data. Chung, Langford, Maz, Abril, Gorelik, Archer, Conn, Full, Grayson, Ibarra, Imundo, Kim, Merkel, Rhee,

Seo, Stone, Vitobaldi, Warner, Byram, Dua, Husainat, Kalot, Lin, Springer, Turgunbaev, Mustafa.

Guidelines

BSR and BHPR guideline for the management of adults with ANCA-associated vasculitis

Eleana Ntatsaki[1,2], David Carruthers[3], Kuntal Chakravarty[4], David D'Cruz[5], Lorraine Harper[6], David Jayne[7], Raashid Luqmani[8], John Mills[9], Janice Mooney[10], Michael Venning[11] and Richard A. Watts[12,13], on behalf of the BSR and BHPR Standards, Guidelines and Audit Working Group

Key words: vasculitis, guideline, management, cyclophosphamide, rituximab.

GUIDELINES

Executive summary

Scope and purpose of the guideline

The ANCA-associated vasculitides (AAVs) are heterogeneous, multisystem disorders characterized by inflammation and necrosis of small and medium blood vessels with unknown aetiology. Three distinct clinico-pathological syndromes have been identified: granulomatosis with polyangiitis (GPA), eosinophilic granulomatosis with polyangiitis and microscopic polyangiitis. The Chapel Hill Consensus Conference (CHCC) in 2012 updated the definitions, however, there are still no validated diagnostic criteria. The aim of this document is to provide guidelines for the management of adults with AAV.

The target audience is rheumatologists, nephrologists, general physicians, specialists, trainees and nurse practitioners. The guideline does not cover the management of other systemic vasculitides or the treatment of children.

This is a short summary of the guideline. The full guideline is available as supplementary material, available at *Rheumatology* Online. For definitions of levels of evidence and recommendation strength see Tables 1 and 2.

Guideline for the management of adults with AAV

We have produced evidence-based recommendations for treatment, giving a grade of recommendation (from A to D) and an algorithm to illustrate the approach to the management of a patient with newly diagnosed AAV.

NICE has accredited the process used by the BSR to produce its guidance for the management of ANCA-associated vasculitis in adults. Accreditation is valid for 5 years from 10 June 2013. More information on accreditation can be viewed at www.nice.org.uk/accreditation. For full details on our accreditation visit: www.nice.org.uk/accreditation.

Table 1 Level of evidence

Category	Evidence
Ia	From meta-analysis of randomized controlled trials
Ib	From at least 1 randomized controlled trial
IIa	From at least 1 controlled study without randomization
IIb	From at least 1 type of quasi-experimental study
III	From descriptive studies, such as comparative studies, correlation studies, or case–control studies
IV	From expert committee reports or opinions and/or clinical experience of respected authorities

Table 2 Determination of recommendation strength

Strength	Directly based on
A	Category 1 evidence
B	Category 2 evidence or extrapolated recommendations from category 1 evidence
C	Category 3 evidence or extrapolated recommendations from category 1 or 2 evidence
D	Category 4 evidence or extrapolated recommendations from category 2 or 3 evidence

Eligibility criteria

Patients with disease consistent with the definitions of ANCA vasculitis as defined by the CHCC in 2012 are eligible for treatment and use of this guideline.

Exclusion criteria

For a diagnosis of ANCA vasculitis, it is important to exclude other causes of systemic illness such as malignancy, systemic infection, drugs, secondary vasculitides or mimics.

Definition of disease states

Remission: well-controlled disease.

(i) On drug remission: prednisolone dose $\leqslant$10 mg/day and a BVAS $\leqslant$1 for $\geqslant$6 months.
(ii) Drug-free remission: $\geqslant$6 months off all treatment for vasculitis.

Relapsing: disease that has been previously well controlled with or without drugs and has become active.

Minor relapse: increase of one or more new or worse minor items and no major BVAS items.

Major relapse: increase of one or more major BVAS item.

Refractory: progressive disease that is unresponsive to current therapy, i.e. remission is not achieved.

Treatment

All patients with AAV should be considered to have severe, potentially life- or organ-threatening disease. Treatment regimens are divided into induction, maintenance and long-term follow-up. Patients who relapse may require a further course of induction therapy (secondary).

The essential principles of management are

(i) Rapid diagnosis
(ii) Rapid initiation of treatment
(iii) Early induction of remission to prevent organ damage
(iv) Maintenance of remission with the aim of eventual drug withdrawal
(v) Prevention of drug toxicity

Primary induction of remission

All patients with newly diagnosed AAV should be assessed for treatment with glucocorticoids (GCs) and i.v. pulse cyclophosphamide (CYC) or rituximab (RTX) (A) (Fig. 1).

Cyclophosphamide

CYC should be given by i.v. pulses initially at 2-week intervals and then at 3-week intervals following the CYCLOPS trial regimen (A). The standard dose is 15 mg/kg, reduced for age and renal function. Because of the lower toxicity, the i.v. regimen is preferred (B). Each individual course of CYC should be $\geqslant$3 months and $\leqslant$6 months (B). Lifetime exposure to CYC should be $\leqslant$25 g since the long-term toxicity of CYC is determined by cumulative dose (C). Patients on CYC should be monitored regularly and the dose should be reduced if there is CYC-induced leucopenia/neutropenia (B). Patients intolerant to CYC can be effectively treated with RTX (B).

Rituximab

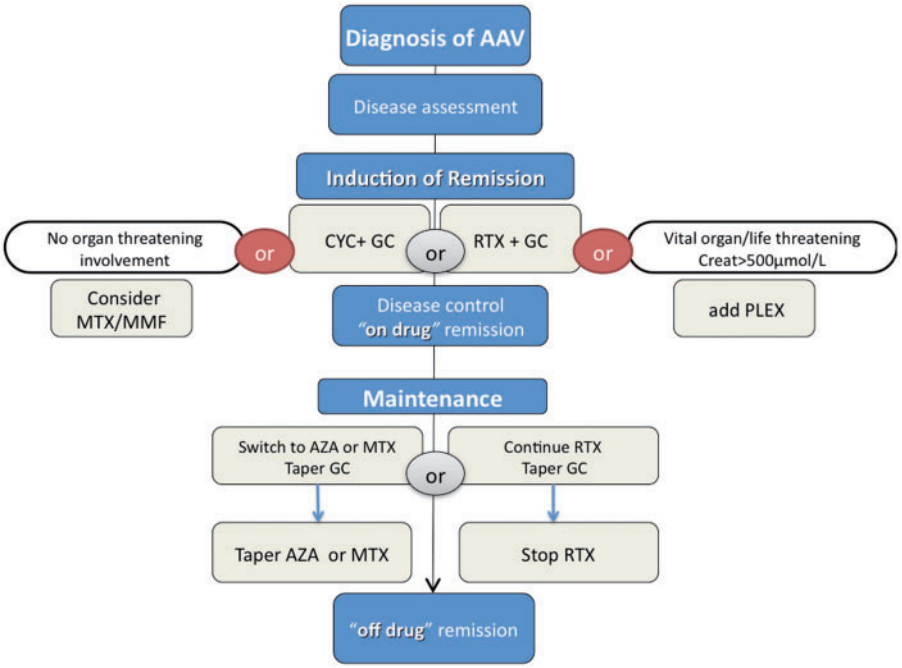
RTX is as effective as CYC for remission induction of previously untreated patients and is preferable when CYC avoidance is desirable, such as in young people at risk of infertility and those at high risk of infection (B). The licensed RTX dosing protocol is 375 mg/m^2/week for 4 weeks (B), however, 1 g repeated after 2 weeks is equally effective (C).

MTX and MMF

MTX (up to 25–30 mg/week) and MMF (up to 3 g/day) are alternative remission induction agents for patients with

Downloaded from https://academic.oup.com/rheumatology/article/53/12/2306/1802843 by guest on 03 February 2023

Fig. 1 Algorithm of the treatment guideline for AAV



evidence of low disease activity and not at risk of suffering organ damage as assessed by the BVAS (A). MTX should not be used in patients with moderate or severe renal impairment (B). MMF may be an alternative to MTX (B).

Plasma exchange

Patients with AAV presenting with severe renal failure (creatinine >500 μmol/l) should be treated with pulsed CYC and GCs, with adjuvant plasma exchange in a centre experienced in its use (B). Treatment with plasma exchange should also be considered in those with other life-threatening manifestations of disease, such as pulmonary haemorrhage (C).

Glucocorticoids

Induction therapy for AAV includes treatment with high-dose GCs in combination with another immunosuppressive agent (CYC, RTX) (A).

GCs are usually given as daily oral prednisolone, initially at relatively high doses (1 mg/kg up to 60 mg) (B) with the dose rapidly reduced to 15 mg prednisolone at 12 weeks (C). Longer courses of GCs may cause increased risk of infection, but may be associated with fewer relapses (A). GC i.v. infusions (250–500 mg methyl-prednisolone) are sometimes given just prior to or with the first two pulses of CYC (C).

Maintenance therapy

Following successful remission, CYC should be withdrawn and substituted with either AZA or MTX (A). MMF (C) or LEF (B) may be used as alternatives for intolerance to or lack of efficacy of AZA or MTX. Patients should continue maintenance therapy for at least 24 months following successful disease remission (B). Patients with GPA or patients who remain PR3-ANCA positive should continue immunosuppression for up to 5 years (C).

RTX may also be used as maintenance therapy, and re-treatment can be decided based on fixed-interval regimens or evidence of relapse (C). The recommended RTX regimen uses 1 g every 4–6 months for 2 years (B).

Withdrawal of treatment

Patients in continual remission for at least 1 year on maintenance therapy should be considered for tapering of GC treatment (D).

Following GC withdrawal, other immunosuppressive therapy may be withdrawn after 6 months (D).

Relapsing disease

Relapsing disease should be treated with an increase in immunosuppression. A minor relapse may be treated with an increase in prednisolone dosage and optimization of concurrent immunosuppression (C). A major relapse may be treated with RTX (A) or CYC with an increase in prednisolone (B). The addition of i.v. methylprednisolone or plasma exchange may also be considered (C). Drivers for relapse need to be identified and addressed and may include infection, malignancy and change of drug therapy (D).

Refractory disease

Refractory disease should only be treated in close collaboration with expert/tertiary centres via a hub-and-spoke

Downloaded from https://academic.oup.com/rheumatology/article/53/12/2306/1802843 by guest on 03 February 2023

model (D). RTX is more effective than CYC in refractory AAV (A). If the patient has not had previous treatment with RTX, then the first choice is RTX (A). Drivers for refractory disease should be sought and clinicians should consider revision of the clinical diagnosis (D).

Assessment and monitoring of disease status

Validated tools [such as the BVAS, Vasculitis Damage Index (VDI) and 36-item Short Form (SF-36)] should be used by trained staff to assess disease activity, extent of damage and quality of life (D). ANCA should be detected using IIF with ELISA to confirm PR3 or MPO specificity (C) and checked at diagnosis, relapse, change of therapy, every 6 months while on treatment and annually while off treatment (B). Results should be available within 1 working day (D). Treatment should not be escalated solely on the basis of an increase in ANCA (B).

Detection and prevention of potential adverse effects of immunosuppressive therapy

The following recommendations should be considered for patients with AAV on immunosuppressive therapy:

(i) Routine blood test monitoring [full blood count (FBC), urea and electrolytes (U&Es), liver function tests (LFTs)] (C)
(ii) Regular urinalysis and mesna for protection against CYC-induced urothelial toxicity (C)
(iii) Serum immunoglobulin measurement before each cycle of RTX therapy (C)
(iv) Trimethoprim/sulfamethoxazole as prophylaxis against *Pneumocystis jiroveci* (B)
(v) Antifungal prophylaxis (C)
(vi) *Staphylococcal aureus* treatment with long-term nasal mupirocin (C)
(vii) Screening for cervical intraepithelial neoplasia (CIN) (female patients) (C)
(viii) Counselling about the possibility of infertility following CYC treatment (C)
(ix) Prophylaxis against osteoporosis where appropriate (A)
(x) Tuberculosis screening (C)
(xi) Vaccination against pneumococcal infection, influenza and hepatitis B (C)
(xii) Cardiovascular and thromboembolic risk assessment (C)

Patient involvement and education

Patients should receive ongoing, tailored education and information about AAV and be encouraged to engage in self-monitoring to improve treatment compliance and long-term outcomes (D). They should have access to information about alternative and complementary therapies that might provide symptomatic relief (D).

Overview of care, collaboration and access to specialist services

Patients with AAV should be managed by a nominated clinician within clinical networks linked with centres of expertise and other specialities within the local organization (D). People with a suspected diagnosis of systemic vasculitis should be rapidly assessed by a specialist physician with an expertise in vasculitis (D). Self-referral mechanisms should be in place for patients, enabling rapid access to a specialist when flaring occurs (D).

Vasculitis annual review, research, audit and registries

Patients with AAV require long-term follow-up and should be encouraged to take part in studies and registries (D). Their annual review should follow a structured format. Audits may need to be conducted on a collaborative basis and may be focused on service delivery and patient-specific areas.

Key quality standards

Rapid access to specialist physicians.
Access to multidisciplinary team.
Provision of personalized education about the disease and its effects.
Access to a full range of therapies.
Opportunity to participate in registries and research projects.

Disclosure statement: R.A.W. has acted as a consultant for Roche and Euro Nippon Kayaku and has received unit support in the form of sponsorships for departmental meetings from multiple providers. D.J. has acted as a consultant for Roche/Genentech, Genzyme, GSK, UCB and Vijorpharma and has received research grants from Roche/Genentech and Genzyme. Introduction

Background

GCA is a large vessel vasculitis affecting older people, with the highest incidence among persons 70–79 years of age [1]. Due to forecasted demographic changes, it has been estimated that between 2014 and 2050, >3 million people will have been diagnosed with GCA in Europe, North America and Oceania [2].

In GCA there is inflammation within the walls of medium and large-sized arteries, with associated intimal hyperplasia [3]. The ischaemia to end organs results in characteristic clinical features such as jaw or limb claudication [4]. Visual loss or stroke may occur in GCA, attributed to vascular occlusion; most GCA-associated visual loss occurs prior to glucocorticoid treatment or shortly after treatment initiation, underlining the importance of immediate treatment if the disease is strongly suspected [5, 6]. The reported proportion of patients with visual loss in GCA varies depending on the GCA case-finding method and method of ascertainment of visual loss; for example, in a UK study recruiting from a rheumatology setting, 17% of 271 patients with GCA reported irreversible visual loss and 1% had stroke [7]. Headache, scalp tenderness, jaw claudication, visual loss and stroke are all classified as cranial manifestations of GCA [4]. In addition, inflammation of the aorta and/or its proximal branches is common in GCA; this is often called large vessel vasculitis outside the head and neck (LV-GCA) and may be asymptomatic or produce non-specific systemic symptoms, such as fever or weight loss. Vascular imaging in GCA demonstrates large vessel involvement, usually with some degree of aortitis, in up to 83% of cases [8]. This large vessel inflammation may lead to later development of vascular stenosis, aneurysm or dilatation, dissection or rupture [9]. A subset of patients with LV-GCA presents with symptoms of a systemic inflammatory syndrome, which can have features of PMR without the classic cranial clinical features of GCA [4]. The true prevalence of this is unknown, as vascular imaging is not routinely performed in PMR at presentation.

Need for the guideline

As GCA is considered a medical emergency, it is treated at the point of diagnosis by clinicians in primary and secondary care who have a wide variety of clinical backgrounds. It is therefore necessary to provide clear guidance about current best practice and the underlying evidence including areas of uncertainty.

Recent years have seen new evidence emerge regarding the diagnosis and treatment of GCA. For this reason, a major revision to the 2010 British Society for Rheumatology (BSR) guideline for the management of GCA [10] was required. We also broadened the remit of the previous guideline to include diagnostic imaging for GCA.

Objectives of the guideline

The objective is to provide guidance for clinicians in the diagnosis and treatment of GCA. The guideline is supported by evidence wherever some evidence exists and by expert consensus where current evidence alone cannot provide a definite answer. The patient population covered by the guideline includes those patients in whom GCA is suspected sufficiently strongly that a decision to initiate glucocorticoid treatment is made. The guideline is not limited to GCA-related temporal (cranial) arteritis but also includes patients presenting with LV-GCA and limited forms of GCA with or without an association with PMR.

The evidence search was restricted to adult humans with GCA or suspected GCA, not limited by ethnicity, age or sex; however, since GCA is extremely rare in patients <50 years of age [1], generalizability below this age limit cannot be assured.

Areas the guideline does not cover

Takayasu arteritis and other forms of vasculitis (e.g. secondary large vessel vasculitis) are not covered by this guideline. The treatment of uncomplicated PMR is outside the scope of this guideline; readers are referred to the most recent BSR and ACR/EULAR guidance on the management of PMR [11, 12]. Guidance regarding immunizations and prophylaxis of glucocorticoid-induced osteoporosis is available elsewhere [13, 14].

Target audience

This guideline is intended for doctors and allied health professionals who work in a primary or secondary care setting and manage patients with suspected and/or established GCA. From a diagnostic perspective, early recognition of suspected GCA by the non-specialist is encouraged, but definitive diagnosis of GCA can be challenging and therefore prompt onward referral to an appropriate specialist is recommended. From a treatment perspective, this guideline is intended to provide a framework by which specialists, general practitioners and patients can work together to deliver optimal care tailored to the individual patient.

Stakeholder involvement

The guideline was developed in accordance with the BSR Guidelines Protocol. Members of the working group co-authored this guideline and are listed at the end of this document with their affiliations. Important stakeholder representation included patient groups (PMRGCAuk, PMR and GCA North East, PMR-GCA Scotland) and the Royal College of Ophthalmology. Individuals on the working group had a range of expertise, including rheumatology, general practice, ophthalmology, specialist rheumatology nursing and systematic review and guideline development methodology, and included patients with personal experience with GCA. There was no representation from industry. Informal feedback was sought at open meetings held at several international rheumatology conferences to ensure that the guideline development process took account of

Downloaded from https://academic.oup.com/rheumatology/article/59/3/e1/5714024 by guest on 03 February 2023

current practice and important clinical questions within the wider rheumatology community, particularly regarding general principles of management.

Prior to defining the Population, Intervention, Comparator, Outcome (PICO) questions, stakeholders were consulted regarding outcomes of importance in GCA [15]. A list of candidate outcomes was identified after feedback from all the stakeholders and from a scoping literature review. A survey was undertaken to prioritize candidate outcomes. A total of 67 patients, 45 rheumatologists, 10 generalists (general practitioners or hospital based) and 7 ophthalmologists responded to the questionnaire. Each outcome was graded based on its relative importance for clinical decision making on a 1–9 point scale [15]. Scores from 1–3 indicated limited importance (not important for decision making), 4–6 indicated important (important, but not critical for decision making) and 7–9 indicated critical (critical for decision making). Outcomes deemed as critical (i.e. score $\geq$7) by at least 70% of physicians and/or patients were considered as candidate outcome measures and this list was refined by the guideline working group for the purpose of defining a list of 'outcomes' for the PICO questions (Supplementary Files, available at *Rheumatology* online).

The GCA Guideline Working Group developed the PICO questions, discussed the evidence collated, iteratively refined the wording of draft recommendations and voted on the final recommendations.

Rigour of development

Scope of literature search and strategy employed

PICO questions

The systematic literature review (SLR) was directed according to predefined questions in PICO. These were written by the working group and feedback was explicitly invited from the patients within the group. The PICO questions were structured as follows:

1. For recommendations on diagnostic imaging tests, the (P) target population comprises patients with suspected GCA, the (I) intervention is the diagnostic test of interest, the (C) comparator is the comparator test or the reference standard and the (O) outcomes are true positives, true negatives, false positives, false negatives, complications related to tests, resource use, inconclusive results and the implication of these items on patient-important outcomes as listed below [16].
2. For recommendations on treatment, the (P) target population comprises patients with a diagnosis of GCA/patients with a high suspicion of GCA above the treatment threshold, (I) intervention and (C) comparator are the alternative management strategies and (O) outcomes as listed below [16].
3. For prognostic factors, the (P) target population comprises patients with a diagnosis of GCA, (I) the presence and (C) the absence of a prognostic factor and (O) outcomes as listed below [17].

A preliminary list of PICO questions was identified by a face-to-face discussion at the first guideline development group meeting followed by an e-mail-based survey of the working group. These preliminary questions were refined and grouped together where appropriate at the second guideline development group meeting. This resulted in a final list of PICO questions (Supplementary Files, available at *Rheumatology* online).

The PICO questions were used to formulate a protocol for the SLR, which was approved by BSR before commencing searches. Screening of the search output was performed by two group members for each topic (diagnostic tests: C. Duftner, S. Appenzeller; therapeutic strategies: C. Dejaco, D. Camellino; prognostic factors: S. Gonzalez-Chiappe, A.W. de Souza) who independently selected full texts, extracted data and performed quality appraisal. Any disagreements between the two group members were resolved by discussion, consulting a third member (S. Mackie, A. Hutchings or A. Mahr, respectively) when no consensus could be reached. The literature search was last updated on 18 June 2018 by G. Reynolds and the outputs appraised by the same group members as before for consistency.

The search strategy of electronic databases is given in the Supplementary Files, available at *Rheumatology* online. Further published studies were identified by hand-searching the reference list of full and review articles and by contacting experts in the field. In addition to this, ClinicalTrials.gov, ISRCTN and the European Union Clinical Trials Register were searched and the literature tracked to identify published trial results. Criteria for selecting articles for full-text review are given below.

Diagnostic studies

We included full research articles of prospective studies involving $>$20 patients and investigating the index test in patients with suspected GCA. We did not evaluate temporal artery biopsy as an index test because of incorporation bias in relation to the reference standard. We excluded diagnostic case–control studies because this type of study design produces estimates of diagnostic accuracy that are not applicable to routine clinical practice [18]; studies where the index (imaging) test had been performed in $>$10% of patients upon treatment with glucocorticoids for $>$1 week (because imaging tests for GCA suffer significant loss of sensitivity after commencing high-dose glucocorticoids; having an imaging test within 1 week of initiating glucocorticoids appears feasible in practice [19]); studies with a reference standard other than clinical diagnosis (without formal criteria), ACR classification criteria and/or temporal artery biopsy result and studies that could not be assigned to any of the PICO questions.

Interventional studies

We included randomized controlled trials (RCTs) involving $>$20 patients with GCA. Observational or non-randomized studies or studies that could not be

Downloaded from https://academic.oup.com/rheumatology/article/59/3/e1/5714024 by guest on 03 February 2023

assigned to any of the interventional PICO questions were excluded.

Prognostic studies

We included prospective and retrospective studies on >100 GCA patients investigating primarily the relevance of any of the prognostic factors of interest. Studies with another research focus (e.g. description of a cohort, interventional trials) were excluded for this part of the SLR. We further excluded studies that did not report the result of a statistical test for association with the outcome. The prognostic factors being investigated should have been in routine clinical use without requiring sophisticated equipment or complex analysis. A minimum time for follow-up in eligible studies was set at 6 months. Because the aim of this part of the SLR was to identify factors that could be used to risk-stratify patients in routine clinical practice, studies that reported exclusively on imaging or laboratory tests with no reference to patient presentation were excluded.

Data extraction

Study details and results were extracted using a data extraction form from included articles by two members of the literature review team according to Grading of Recommendations Assessment, Development and Evaluation (GRADE) methodology [20]. The preliminary data extraction form was piloted in five identified articles and evaluated for completeness and handling. This data extraction form included the following items: authorship and publication, design, main study population, primary study objective(s), links/overlap with other studies, study inclusion criteria, characteristics of participants, definition of intervention/exposure and control, definition of outcome, method of statistical analysis, length of follow-up, losses to follow-up, missing data, discrete/continuous data (counts, means, standard deviations etc.), measures of effect and uncertainty and any other information relevant to quality assessment.

Additional parameters extracted relevant to diagnostic studies included the use of glucocorticoids before performance of imaging, disease characteristics [number (%) of patients fulfilling clinical criteria for GCA, number (%) of patients with positive temporal artery biopsy, number (%) of patients with large vessel GCA], technical aspects (imaging devices used, elementary lesions and structures investigated, blinding of the index test to a reference standard), index test, reference standard, diagnostic performance [raw data to calculate sensitivity, specificity, positive (LR+) and negative likelihood ratio (LR−)] and parameters required for assessment of study quality (risk of bias). Additional data extracted relevant to prognostic factors included adjusted and unadjusted odds ratios (ORs), relative risks (RRs) or hazard ratios (HRs) and information relevant to quality assessment.

Quality assessment

We evaluated the quality of evidence using the approach set out by GRADE [20, 21] and implemented as follows:

1. Risk of bias: Confidence in the estimate of the effect decreases if studies have major limitations that may bias their results. For diagnostic studies, risk of bias was assessed using the QUADAS-2 tool [22]. For interventional studies, the following factors were considered [20]: randomization procedure and sequence generation, allocation concealment, blinding of patients and assessor, completeness of outcome reporting (attrition bias: losses of follow-up, adherence to the intention-to-treat analysis or stopping the trial early for benefit) and selective outcome reporting. For prognostic studies, risk of bias was investigated using the following questions [17]:
   - Was there a representative and well-defined sample of patients? Was selection bias avoided?
   - Was follow-up sufficiently long and complete?
   - Were objective and unbiased outcome criteria used? Were methods used to determine/measure outcomes adequate?
   - Were all characteristics of patients known or suspected to affect the outcome recorded?
   - Was there adjustment for important prognostic factors, including age, sex, ESR, ischaemic manifestations (amaurosis fugax, jaw claudication, limb claudication), extracranial manifestations, symptom duration, comorbidities, constitutional symptoms and smoking?
2. Inconsistency of results: Confidence in the estimate of the effect decreases if there is variability in results (heterogeneity) across studies and investigators fail to identify a plausible explanation.
3. Indirectness of the evidence: Confidence in the estimate of the effect decreases if there are differences between the population, intervention, comparator or outcome of interest and those included in the systematic review studies.
4. Imprecision: Confidence in the estimate of the effect decreases if the systematic review includes relatively few patients and few events and thus has wide confidence intervals and/or the extremes of the confidence intervals are close to the null effect.
5. Publication bias: Confidence in the estimate of the effect decreases if there is evidence that some studies were not reported.

Evidence generated from prospective diagnostic accuracy studies, RCTs and longitudinal cohort studies investigating prognostic factors started as high quality but was downgraded if any of the above limitations was present.

After assessing these five domains the overall quality of evidence (QoE) was assessed as:

1. High quality evidence [indicated by ++++ (A) – further research is very unlikely to change our confidence in the estimate of effect]

Downloaded from https://academic.oup.com/rheumatology/article/59/3/e1/5714024 by guest on 03 February 2023

2. Moderate quality [indicated by +++ (B) – further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate]
3. Low quality [indicated by ++ (C) – further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate]
4. Very low quality [indicated by + (D) – any estimate of effect is very uncertain]

Preparing the evidence report

Evidence tables were prepared by the literature review team for each PICO question using Review Manager (RevMan; Cochrane Collaboration, London, UK) and GRADE profiler (GRADEpro) software. The evidence profiles contained the following specific information:

Diagnostic studies

Diagnostic studies included direct outcomes (true positives, true negatives, false positives, false negatives, sensitivities and specificities; complications of the index test and of the reference standard; resource use), the number of studies and quality assessment related to each of these outcomes and the effect estimate (i.e. number of individuals classified per 1000 people) according to different pretest probabilities [low (<20%), intermediate (20–50%) and high (>50%) pretest probability].

Interventional studies

Interventional studies included benefits and harms for each outcome across studies, the assumed and corresponding risk for comparators and interventions (95% CI), the absolute and relative effect (95% CI), the number of participants/number of studies, the number needed to treat and the QoE, including quality factors for each critical and important outcome.

Prognostic studies

Prognostic studies included ORs, RRs or HRs as well as corresponding *P*-values, both unadjusted and (where available) adjusted for confounders. Results of quality appraisal were also reported.

Whenever possible, meta-analyses using fixed effects methods (interventional studies) or random effects methods (diagnostic, prognostic studies) were conducted to combine the results of studies for each PICO question.

Statistical heterogeneity was assessed by considering the chi-squared test for significance at $P < 0.1$ and an I^2 inconsistency statistic of >50% to indicate significant heterogeneity. Where significant clinical heterogeneity was present, analysis of individual studies and/or subanalyses investigating studies with comparable design and quality was conducted.

Methods used to formulate the recommendations

General principles statements

GRADE recommends that where certain principles of diagnosis and treatment of a disease are generally agreed upon by the medical community, these should be stated in terms of 'good practice statements' [23]. Here we call these 'general principles' and they are a description of generally accepted best medical practice as evidenced by consensus within our Guideline Working Group. They are not necessarily evidence-based, but form the clinical context within which the evidence-based recommendations should be understood.

General principles statements in relation to GCA were drafted and iteratively refined by means of multiple rounds of e-mail consultation within the guideline working group, including patient representatives, as well as wider consultation by presentation and discussion at international rheumatology meetings. The final versions were voted on by the working group and a consensus score generated for each statement, defined as the mean value of scores of all the individual working group members.

Forming guideline recommendations

Using the evidence profiles, recommendations were proposed for each key question according to the GRADE methodology [24]:

The GRADE system offers two grades of recommendations: 'strong' and 'conditional'.

This grade is determined by the QoE, balance between desirable and undesirable effects, values and preferences of patients and use of resources.

The evidence on prognostic factors was used to build subgroups of GCA patients with different risk profiles concerning patients' important outcomes rather than formulating individual recommendations on prognostic factors. Treatment recommendations have been tailored to these subgroups given that the trade-off between benefit and harm, values and preferences as well as consideration regarding resource use may vary according to the presence or absence of risk factors.

The recommendations process was conducted in two stages:

1. The quality of evidence was discussed at international meetings and webinars.
2. Recommendations were formulated that were iteratively refined via webinars and e-mail.

Finally, the working group voted by scoring each recommendation on a 0–10 scale. The consensus score was defined as the mean of all scores received.

The overall QoE for each recommendation was summarized using the GRADE QoE scale, as per the BSR Guidelines Protocol 2017.

Limits of search and search dates

The following electronic databases were searched from their inception dates, noted in parentheses, to the

Downloaded from https://academic.oup.com/rheumatology/article/59/3/e1/5714024 by guest on 03 February 2023

present: Ovid MEDLINE (1946), Embase (1988), Cochrane Central Register of Controlled Trials (1996) and Cochrane Systematic Reviews (1993). The search was last updated on 23 June 2018.

Because of the need for quality appraisal by a consistent team of reviewers, the search was limited to articles published in English.

When will the guideline be updated?

The guideline will be updated after 3 years; publication of a major new clinical trial may trigger a partial revision.

The guideline

Eligibility

- Patients with suspected GCA (for diagnostic tests)
- Patients with confirmed GCA (for treatment recommendations)

Exclusions

- Takayasu arteritis
- PMR (unless there is also a diagnosis of GCA)

General principles

General principles are not the same as evidence-based recommendations, but are presented here to summarize best practice.

How should suspected GCA be treated?

1. Patients in whom GCA is strongly suspected should be immediately treated with high-dose glucocorticoids. Consensus score: 9.61.

'Strongly suspected' GCA means that in the assessing clinician's judgement, GCA is a more likely explanation for the patient's symptoms than any other condition. The assessing clinician may take into account GCA symptoms, signs and laboratory tests (such as acute phase markers) [25, 26]. The risk of toxicity caused by short-term glucocorticoid treatment commenced in patients with initial strong suspicion of GCA but then diagnosed with an alternative condition is acceptably low as long as a full diagnostic evaluation is performed promptly and it is acknowledged that a suspicion of GCA is not the same as a diagnosis of GCA. For doses, see below.

How quickly should patients with suspected GCA be referred for evaluation?

2. GCA is a medical emergency. Each local healthcare organization should have information available to front-line clinicians, such as general practitioners and clinicians working in acute care, on how to refer patients with suspected GCA urgently for local specialist evaluation. Patients should be evaluated by a specialist ideally on the same working day if possible and in all cases within 3 working days. Consensus score: 9.17.

Rapid specialist evaluation is a key principle of management of GCA, therefore 'fast-track' referral pathways for urgent specialist evaluation of suspected GCA are beneficial. On suspicion of GCA, primary care providers should initiate glucocorticoids alongside an urgent referral to the local GCA pathway. In retrospective reports from centres that have set up fast-track referral pathways, initial diagnostic evaluation and treatment of patients with suspected GCA within 24 h of referral has been associated with a reduction in reported rates of GCA-related sight loss compared with conventional care pathways [27, 28]. In a prospective, multicentre UK study, clinical evaluation, vascular ultrasound and temporal artery biopsy were all undertaken within 1 week of commencing high-dose glucocorticoid therapy for suspected GCA [19]. The success of fast-track referral pathways depends on appropriate selection of patients for referral and therefore education of clinicians in primary and secondary care is crucial.

To whom should patients with suspected GCA be referred?

3. Patients with suspected GCA should be evaluated by a clinician with appropriate specialist expertise, usually a rheumatologist. Patients presenting with a history of new visual loss (transient or permanent) or double vision should be evaluated as soon as possible on the same calendar day by an ophthalmologist. Consensus score: 9.61.

The reason for needing a full, prompt diagnostic evaluation by a clinician with appropriate specialist expertise is that undiscerning use of high-dose glucocorticoids may mask other diseases and can complicate the diagnostic workup [12, 25]. Where the diagnosis is difficult, opinions from specialists from multiple disciplines can be of value. This includes the interpretation of specialized investigations for GCA and consideration of alternative diagnoses. Ophthalmological evaluation is essential where there is visual loss, of which there are various possible causes in GCA [29, 30].

What evaluations should be performed when starting treatment?

4. When starting glucocorticoids for suspected GCA, diagnostically relevant symptoms and signs should be documented. Blood should be taken for full blood count, CRP and ESR before or immediately after commencing high-dose glucocorticoids. If GCA is strongly suspected, the first dose of glucocorticoid can be given without waiting for laboratory results. Consensus score: 9.61.

Diagnostically relevant symptoms and signs of GCA include headache; scalp tenderness/hyperaesthesia; jaw or tongue claudication; temporal artery tenderness, nodularity or reduced pulsation; visual manifestations including diplopia or changes to colour vision; limb claudication; PMR (pain and stiffness of the shoulder and hip girdles) and fever, sweats or weight loss. Less commonly, patients may have carotidynia, audiovestibular symptoms, dry cough or indications of tongue or scalp ischaemia that may precede necrosis.

However, as none of the above-mentioned symptoms is entirely specific (or pathognomonic) for GCA, and many are very non-specific, each is of limited use if

Downloaded from https://academic.oup.com/rheumatology/article/59/3/e1/5714024 by guest on 03 February 2023

Table 1 A proposed list of clinical assessments that could be carried out at or near diagnosis of GCA

History and examination	Investigations
• Height and weight • Features of GCA relevant to prognosis: fever, sweats or weight loss; ischaemic manifestations (jaw claudication, tongue claudication) • Signs and symptoms indicating involvement of extracranial arteries, e.g. bruits, different blood pressures in the two arms and limb claudication • Ophthalmological evaluation for patients with transient or permanent visual loss or diplopia • History of comorbidities and medications that might predispose to glucocorticoid-related adverse effects, including infection, hypertension, diabetes, osteoporosis, low-trauma fracture, dyslipidaemia, peptic ulcer and psychiatric adverse effects • Features that may suggest an alternative diagnosis, e.g. neurological deficits, very severe constitutional symptoms or localised ear, nose and throat signs	• Measures of activity of GCA: laboratory markers of inflammation (CRP for all patients, plus either ESR or plasma viscosity) and full blood count (platelet count may be elevated in GCA) • Consider serum protein electrophoresis and urine Bence–Jones protein/serum free light chains if ESR elevated out of proportion to CRP • Baseline laboratory tests of major organ system function (plasma glucose, renal and liver function tests, calcium and alkaline phosphatase) • Screening tests for risk of serious infection[a] (may include urine dipstick, chest radiograph and tests for latent tuberculosis according to local or national protocol) • Screening tests for osteoporosis risk[a] (may include TSH, vitamin D, bone density test, DXA)

[a]Screening tests for infection and osteoporosis to be considered in light of relevant local and national guidelines. TSH, thyroid stimulating hormone; DXA, dual-energy X-ray absorptiometry.

taken in isolation [26], and the differential diagnosis must also be considered. GCA causes an elevation in platelet count, CRP and ESR. Plasma viscosity can be used where ESR is unavailable. These markers all decrease with glucocorticoid therapy, therefore all patients should have blood drawn prior to starting treatment, unless there is evidence of critical ischaemia such as visual loss or diplopia and no immediate access to phlebotomy.

What evaluations should be performed soon after starting treatment for GCA?

5. Patients treated for GCA should be evaluated for features of the disease relevant to the prognosis, such as clinical and laboratory features of a marked inflammatory response at diagnosis, ischaemic manifestations such as transient visual loss or jaw/tongue claudication and signs or symptoms indicating involvement of the aorta and its proximal branches, and for comorbidities relevant to treatment, such as diabetes mellitus, hypertension and bone fracture risk. Consensus score: 9.53.

Assessments to be performed in all patients with GCA are detailed in Table 1. As well as confirmatory tests for GCA (see Key Recommendation 1), alternative explanations for patients' symptoms should be considered, particularly if these confirmatory tests are negative. Factors relating to prognosis [risk factors (prognostic) PICO questions 1–6] were reviewed. Overall, insufficient evidence was found to be able to stratify patients with proven GCA to different management strategies on the basis of risk factors considered: age, sex, acute phase reactants, PMR status, large vessel involvement in GCA, atherosclerotic disease, glucocorticoid responsiveness or histological features of GCA. Nonetheless, these features remain important diagnostically and/or when assessing for risk of glucocorticoid-associated adverse effects.

Risk factors for visual loss: Studies reporting risk factors for permanent visual loss in GCA yield variable results. In a single-centre study of 339 consecutive biopsy-proven cases presenting over a 39-year period, in which clinical features were prospectively recorded by an internist in a 176-item structured questionnaire, 53 patients had permanent visual loss. In multivariable regression modelling, older age, history of transient visual loss and jaw claudication were independent predictors of visual loss, while fever and rheumatic symptoms were protective [31]. Similar findings were reported in an earlier retrospective study of irreversible cranial ischaemic complications in 200 patients, with transient diplopia also identified as a potential risk factor [32].

Hypertension and ischaemic heart disease were also identified as potential risk factors for cranial ischaemic complications in studies from Italy and Spain [33, 34]. In an international multicentre observational study reporting data from 433 GCA patients from 26 countries, 34 patients developed complete loss of vision in one or both eyes at 6 months. After adjusting for age and sex, the strongest risk factor for this was peripheral vascular disease recorded at baseline (the effect size was similar when restricting the case definition to biopsy-proven GCA) [35].

Risk factors for aortic aneurysms: Inflammation of the aorta is associated with subsequent development of aortic dilatation or aneurysm [36], and those GCA patients with dilatation of the subclavian arteries were found to be more likely to have subsequent aortic aneurysm than those with GCA-related subclavian stenosis [37]. Possible risk factors for aneurysm development in GCA are smoking, male sex, hypertension and pre-existing cardiovascular disease as well as inflammation of the aorta or its proximal branches [37–41]. However, the evidence about risk factors for aneurysm development in GCA is at present not sufficient to define high-

Downloaded from https://academic.oup.com/rheumatology/article/59/3/e1/5714024 by guest on 03 February 2023

risk subgroups to select GCA patient subgroups for aortic imaging.

Chest radiography involves minimal radiation exposure but is insensitive to early thoracic aortic aneurysms [42]. French recommendations suggest routine aortic imaging at GCA diagnosis and every 2–5 years thereafter [43]. However, aortic imaging as a routine screening test for all GCA patients remains of uncertain cost-effectiveness and the optimal method and timing of imaging in this context is still unclear [44]. Therefore clinicians are advised to use their own discretion regarding selection of patients for aortic imaging.

Risk factors for prolonged treatment course: A 'strong inflammatory response' (defined as three or four of the following features: fever, weight loss, ESR $\geq$85 mm/h and haemoglobin $<$11 g/dl) has been associated with a higher relapse rate and prolonged treatment course [45–47]. Imaging evidence of LV-GCA may be associated with prolonged glucocorticoid treatment compared with patients with cranial GCA who did not have imaging evidence of LV-GCA [36, 48].

It is best practice for the prescriber of glucocorticoid therapy to ensure that patients are evaluated for hypertension and hyperglycaemia (blood glucose for acute changes and/or HbA1c to identify patients that might be at greater risk) within the first 2 weeks of commencing high-dose glucocorticoids. Comorbidities relevant to glucocorticoid toxicity include diabetes mellitus, osteoporosis and bone fracture. Generally, toxicity increases with glucocorticoid dose and duration [49]. Symptoms of and/or exposure to serious infections should be assessed in all patients starting glucocorticoids, considering the local prevalence of these infections. It is suggested that a chest radiograph and dipstick urinalysis should be performed. Exposure to tuberculosis should be discussed and screened according to national guidelines [50].

Oral glucocorticoids can rarely increase intraocular pressure or worsen pre-existing primary open-angle glaucoma. If there is glaucoma or ocular hypertension present, or a history of being a glaucoma suspect or glaucomatous risk factors (such as connective tissue disease, type I diabetes, a first-degree relative with primary open-angle glaucoma or high myopia), screening should be performed by a suitably trained eye professional [51].

For ongoing care via a shared care model, patients with GCA should see a clinician with appropriate expertise at least every 2–8 weeks during the first 6 months, then every 12 weeks during the second 6 months, every 12–24 weeks during the second year and additionally as indicated in case of relapse or as glucocorticoid therapy is tapered and discontinued. This visit schedule is based on the higher likelihood of new treatment-related adverse events and the need for treatment dose adjustment early in the treatment course while glucocorticoid doses are still high. However, this should be adapted for the individual patient. Each follow-up visit should include at least a full history, targeted physical examination and measurement of at least a full blood count, ESR and/or CRP, plus follow-up of any abnormalities relevant to the individual patient as well as drug-specific screening for toxicity.

How should ongoing management of GCA be individualized?

6. Full assessment of the disease and comorbidities and consideration of the patient's personal priorities should inform decisions about glucocorticoid tapering and initiation of additional treatments such as glucocorticoid-sparing therapies. Involvement of and clear communication with primary care physicians is critical, especially for management of multimorbidity. Consensus score: 9.67.

Management of patients with GCA should include attention to comorbidities and the impact of glucocorticoid toxicities in order to individualize the standard glucocorticoid tapering schedule (Table 2). PICO questions on the prevention of glucocorticoid-induced osteoporosis and immunization in GCA were not included; there are published guidelines on these matters [13, 14]. Although it is customary to co-prescribe proton pump inhibitors with high-dose glucocorticoid therapy, especially in older patients, it has recently been suggested that lower glucocorticoid doses may not always routinely need co-prescription of a proton pump inhibitor [53]. Local or national guidance should be followed.

Glucocorticoid therapy increases susceptibility to infections but may also decrease the efficacy of vaccinations; live vaccines are contraindicated in patients receiving high-dose glucocorticoid therapy ($>$20 mg prednisolone daily for $\geq$2 weeks) [54]. Patients without a history of chicken pox (varicella zoster virus infection) should be advised to avoid close contact with people who have chickenpox or shingles and to seek urgent medical advice if they have been exposed.

What education should patients be offered?

7. All patients with GCA should be provided with information about GCA and its treatment. Patients should receive advice on diet, physical activity and stopping smoking. Consensus score: 9.47.

Information should be available in written format and ideally in multiple formats. Dietary considerations include mitigating the potential effects of glucocorticoid therapy on body weight, post-prandial glycaemia and bone fracture risk. Recommendations on physical activity in inflammatory arthritis and osteoarthritis are available [55] and there have also been suggestions of benefit in other inflammatory vascular diseases [56], but advice needs to be tailored to the individual patient with GCA, particularly if there are comorbidities.

Particular considerations in GCA may include physical deconditioning as a result of the inflammatory disease, vascular stenosis to the limbs and the role of exercise in stimulating collateral formation and the psychological benefits of exercise in mitigating the impact of the disease on the patient. Particular considerations with patients receiving long-term glucocorticoid treatment

Downloaded from https://academic.oup.com/rheumatology/article/59/3/e1/5714024 by guest on 03 February 2023

Table 2 A typical glucocorticoid tapering schedule for GCA

Daily prednisolone dose	Example rate of reduction in daily prednisolone dose	Notes
40–60 mg oral prednisolone: initial dose for patients with active GCA	Continue at same dose until GCA symptoms and acute phase markers resolve	Purpose: induction of clinical remission
In clinical remission and >20 mg prednisolone	Reduce daily dose by 10 mg every 2 weeks	Aim to reach 20 mg prednisolone once the patient has been in remission for 4–8 weeks
In clinical remission, >10 mg prednisolone but <20 mg	Reduce daily dose by 2.5 mg every 2–4 weeks	If symptoms suggestive of GCA relapse occur during taper, consult Table 3
In clinical remission and on ≤10 mg prednisolone	Reduce daily dose by 1 mg every 1–2 months	

This is an example of a typical glucocorticoid taper schedule, based on that described in the 2010 BSR guidelines for GCA [10] and similar to the control arm of a recent GCA clinical trial [52]. High-quality evidence comparing different glucocorticoid taper schedules in GCA is not available. Alternative approaches include, for example, reducing prednisolone by 10 mg/week in patients who are in remission at >20 mg daily and/or reducing the dose slower than stated here in patients who are on ≤5 mg daily. In all cases, taper schedules should be individualized based on the patient. For relapse management, see Table 3.

Table 3 Examples of symptoms that may signify relapse of GCA during glucocorticoid taper that require further evaluation and, if judged to be due to GCA relapse, escalation of glucocorticoid treatment

Symptom	Possible significance in a patient with GCA	Action to consider if symptom is judged to be due to GCA relapse
Return of headache symptoms	Possible GCA relapse without ischaemic manifestations	Return to previous higher prednisolone dose
Jaw or tongue claudication	Possible GCA relapse with ischaemic manifestations	Consider high-dose oral prednisolone (40–60 mg) with or without glucocorticoid-sparing agent
Weight loss, fever, night sweats, anaemia, persistent acute phase response, new/recurrent PMR symptoms, limb claudication, abdominal pain or back pain	Possible GCA-related inflammation of the aorta and/or its proximal branches	Investigate with vascular imaging (MRI, CT or FDG-PET/CT); consider increasing oral prednisolone and/or adding glucocorticoid-sparing agent

This table outlines how new symptoms in GCA patients, in the absence of other risk factors or significant comorbidities, may influence management decisions. New visual loss or diplopia should be urgently evaluated by an ophthalmologist. Acute phase markers should be measured and, if found to be elevated, may increase the clinical suspicion of GCA relapse. At present, the only agents with any evidence for glucocorticoid-sparing in GCA are methotrexate and tocilizumab.

may include myopathy, which typically develops after weeks or months of glucocorticoid therapy (particularly at high doses); insulin resistance limiting the ability of skeletal muscle to take up glucose and store glycogen; bone fragility and central adiposity. Exercise can also be beneficial for improving balance and general mobility, which may be affected by alterations to vision and biomechanics.

The role of exercise programmes in GCA has not been formally evaluated in clinical studies. Patients should be signposted to relevant patient support groups or charities as sources of peer support. Patients should be advised of potential symptoms of glucocorticoid withdrawal, although these are uncommon in practice. Patients should be advised about alteration of their glucocorticoid dose in intercurrent illness, especially including advice for seeking emergency attention if they suffer a vomiting illness necessitating parenteral glucocorticoid.

What plans should be made for possible future GCA relapses?

8. During glucocorticoid taper and after glucocorticoid cessation, patients should be informed what symptoms may suggest GCA relapse and what action the patient should take in these circumstances, including the first point of contact for medical advice and how to contact the team providing specialist care. Consensus score: 9.81.

Examples of actions to consider if new GCA-attributable symptoms develop are given in Table 3.

Specific recommendations for diagnostic tests in suspected GCA

As affirmed in the 2010 BSR/British Health Professionals in Rheumatology guideline, there is an urgent need for confirmation of disease in every suspected case of GCA [10]. In the 2010 guidance, it was recommended that

Downloaded from https://academic.oup.com/rheumatology/article/59/3/e1/5714024 by guest on 03 February 2023

temporal artery biopsy was desirable in every case of suspected GCA. In this edition, this recommendation has been updated in view of new evidence regarding imaging tests for diagnosis of GCA.

Which additional confirmatory diagnostic tests should be performed in all patients with suspected GCA? (PICO 1, 2)

Diagnostic accuracy may be expressed as sensitivity and specificity, or as a likelihood ratio; this information can be combined with the pretest probability (established on clinical grounds) to select and interpret the results of confirmatory diagnostic tests. Compared with biopsy, imaging tests such as ultrasound have the advantage of access to both superficial temporal arteries in their entirety. Most diagnostic accuracy studies have focussed on the role of ultrasound ($n = 16$) or MRI ($n = 7$). One study addressed the role of FDG-PET and another study examined the role of FDG-PET and CT angiography (CTA) for GCA diagnosis.

Seven studies (519 patients with suspected GCA, of whom 169 were diagnosed with GCA) compared the ultrasound 'halo' sign with a clinical diagnosis of GCA, giving a pooled sensitivity of 79% (95% CI 73, 84) and pooled specificity of 94% (95% CI 90, 96) [57–63]. The QoE was +++; downgrading was performed because of risk of bias in four of seven studies. One of these studies included 12 patients with a final diagnosis of LV-GCA [58].

Five studies (185 patients with suspected GCA, of whom 57 were diagnosed with GCA) compared the ultrasound 'halo' sign with temporal artery biopsy, giving a pooled sensitivity of 74% (95% CI 63, 83) and pooled specificity of 81% (95% CI 73, 88) [61–65]. The QoE was +; downgrading was performed because of high risk of bias in all five studies and because of inconsistency. Patients with LV-GCA were not evaluated in these studies.

Two studies (140 patients with suspected GCA, of whom 67 were diagnosed with GCA) compared the ultrasound 'compression' sign of temporal arteries with ACR criteria–based diagnosis of GCA, giving a pooled sensitivity of 79% (95% CI 67, 88) and a pooled specificity of 100% (95% CI 95, 100) [57, 66]. The QoE was ++; downgrading was performed for risk of bias in one of the studies and because both studies were performed by the same research group. The ACR criteria for GCA, which are not suitable for clinical diagnosis, served as the reference standard in both studies.

Three studies (560 patients with suspected GCA, of whom 327 had a clinical diagnosis of GCA) compared the diagnostic performance of ultrasound abnormality (defined as any one of halo, stenosis or occlusion) with clinical diagnosis of GCA, giving a pooled sensitivity of 61% (95% CI 56, 67) and pooled specificity of 86% (95% CI 81, 90) [19, 63, 67]. The QoE was ++; downgrading was performed for risk of bias in all three studies and for inconsistency.

Four studies (563 patients with suspected GCA, of whom 180 had a positive temporal artery biopsy) compared the diagnostic performance of ultrasound abnormality (defined as any one of halo, stenosis or occlusion) with temporal artery biopsy, giving a pooled sensitivity of 81% (95% CI 74, 86) and pooled specificity of 74% (95% CI 70, 79) [19, 63, 67, 68]. The QoE was ++; downgrading was performed for risk of bias in three of the four studies and for imprecision.

Neither clinical diagnosis nor temporal artery biopsy are perfect reference standards for evaluating the diagnostic accuracy of ultrasound for GCA, because neither of these are themselves 100% accurate. Clinical diagnosis is based on clinical symptoms, signs and laboratory tests, each of which are imperfect markers for GCA.

A positive temporal artery biopsy showing features of inflammation characteristic of GCA such as giant cells or panarteritis [69] confirms the diagnosis of GCA. Although the true sensitivity of temporal artery biopsy is not precisely known, it is accepted that its sensitivity is substantially <100%; this is supported by the histological observation of skip lesions in some cases. An imperfect reference standard would result in underestimation of the diagnostic accuracy of ultrasound. When using clinical diagnosis as a reference standard it is important that this is made independently of the index test result in order to avoid bias. This may be done by blinding of the diagnostician to the index test result. Notably a large prospective UK study assessing the diagnostic value of ultrasound addressed this issue by blinding the patient, the treating clinician and the investigator to the ultrasound result [19].

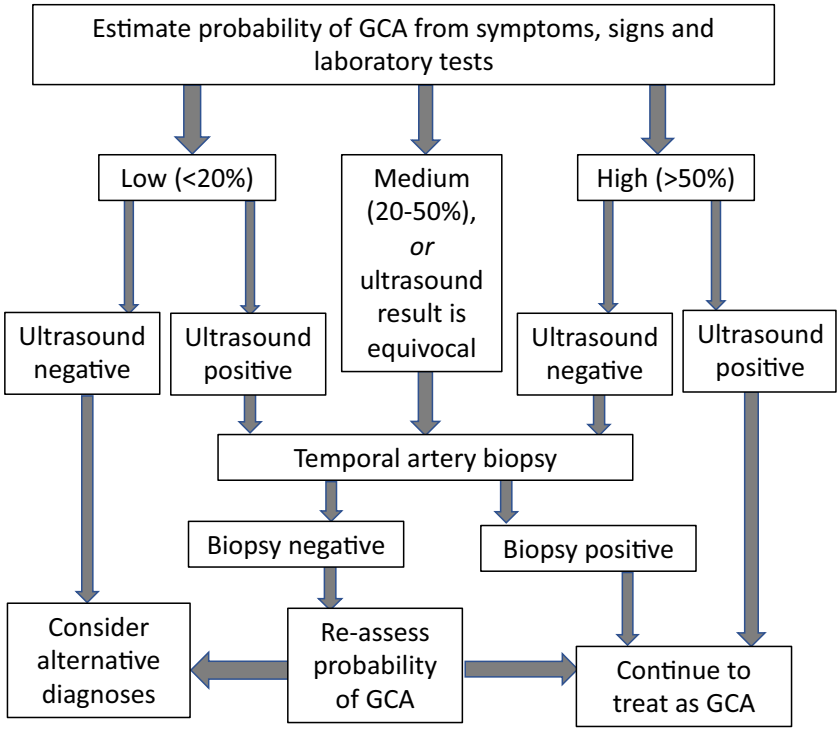
Ultrasound was found to be more sensitive but less specific than biopsy for diagnosis of GCA, was cost effective and provided a method for reducing the number of patients who need a temporal artery biopsy [19]. Overall, the pooled positive and negative likelihood ratios for ultrasound appear to support its use either for ruling out GCA in low-probability cases or for confirming GCA in high-probability cases (Supplementary Files, available at *Rheumatology* online and Fig. 1). Ultrasound of the axillary arteries might add extra diagnostic information to ultrasound of the temporal arteries [70].

Six studies (500 patients with suspected GCA, of whom 268 were finally diagnosed with GCA) compared cranial artery MRI (vessel wall oedema and contrast enhancement) with clinical diagnosis, giving a pooled sensitivity of 75% (95% CI 69, 80) and a pooled specificity of 89% (95% CI 84, 93) [71–76]. The QoE was ++; downgrading was performed for risk of bias in five of the studies and because five of the six studies were performed by the same research group; sensitivity was somewhat lower in the study performed by a separate group [76].

Five studies (397 patients with suspected GCA, of whom 171 had positive temporal artery biopsy) compared cranial artery MRI (vessel wall oedema and contrast enhancement) with temporal artery biopsy, giving a pooled sensitivity of 94% (95% CI 90, 97) and specificity of 79% (95% CI 73, 84) [71–74, 76]. The QoE was +; downgrading was performed for risk of bias in five of the studies, for inconsistency and for likely publication bias.

Downloaded from https://academic.oup.com/rheumatology/article/59/3/e1/5714024 by guest on 03 February 2023

FIG. 1 A possible approach to using rapid-access vascular ultrasound to assist in clinical diagnostic decision making in suspected cranial GCA



This figure illustrates a possible approach to using rapid-access vascular ultrasound, if available, in suspected GCA. Estimation of the probability of GCA is based on all information available (symptoms, signs, laboratory tests and alternative non-GCA explanations for the clinical picture) and can be updated based on new information (clinical course, result of temporal and axillary ultrasound and/or results of temporal artery biopsy). This assessment is based on clinical judgement and should ideally be performed by an individual with specialist expertise. Note that for a medium (20–50%) estimated probability of GCA, it may be useful to perform an ultrasound prior to biopsy, in case the biopsy is negative. For a high clinical probability of GCA, a positive ultrasound alone may be sufficient, as illustrated here; however, in these cases it is still acceptable to perform biopsy in addition to ultrasound in order to further increase diagnostic certainty. In the absence of clinical features of cranial GCA, temporal artery biopsy can still be positive, but imaging of the extracranial large vessels may be considered instead of, or in addition to, temporal artery biopsy. Recently, various clinical prediction rules have been proposed to assist clinicians in the estimation of probability of GCA; the performance of a clinical prediction rule developed in another setting should ideally be checked using local audit data prior to adopting into local clinical practice. If rapid-access vascular ultrasound is not available, patients treated for suspected GCA should all have a temporal artery biopsy. None of these tests should delay the prescribing of high-dose glucocorticoid therapy for patients with strongly suspected GCA.

Overall, MRI of the cranial arteries appears to be potentially useful for ruling out GCA if the result is negative, but false-positive test results could occur, such that MRI of the cranial arteries would not be first choice for a confirmatory test in GCA [76]. Other issues of relevance to cranial vascular MRI are low availability of high-resolution 3T MRI equipment and expertise, higher costs and possible adverse effects of contrast agents.

In contrast to the 2010 guideline, where the authors outlined that imaging techniques are promising for diagnosis and monitoring of GCA [10], in this guideline there is now sufficient evidence, taken together, to state that all patients with GCA should have at least one confirmatory diagnostic test, which could be either temporal artery biopsy or temporal and axillary artery ultrasound. However, temporal artery biopsy and ultrasound differ in their positive and negative likelihood ratios for GCA, with biopsy having relatively greater 'rule-in' value and ultrasound having relatively greater 'rule-out' value (Supplementary Files, available at *Rheumatology* online). Selection of the most appropriate confirmatory diagnostic test(s) therefore requires an assessment of the pre-test probability as outlined elsewhere [77]; if both ultrasound and biopsy are possible, an approach to this is suggested in Fig. 1.

The ultrasound halo diminishes in size during the first week of glucocorticoid therapy, indicating that the sensitivity of the test is likely to depend on the delay between initiation of glucocorticoid therapy and the ultrasound test [19]. Ultrasound is operator-dependent and requires

Downloaded from https://academic.oup.com/rheumatology/article/59/3/e1/5714024 by guest on 03 February 2023

adequate training. Ultrasound performs best in the 'fast-track' setting, assuming rapid access, good technical equipment and high expertise with this method. With ultrasound, the non-compressible 'halo' sign is the most important finding suggesting GCA [78]. Temporal artery biopsy should be performed by a surgeon experienced in this procedure and samples should be at least 1 cm in length post-fixation. The pathologist evaluating the biopsy should be experienced in diagnosing GCA.

Data from the Temporal Artery Biopsy versus Ultrasound in the Diagnosis of Giant Cell Arteritis study [19] suggested significant variation between pathologists in the interpretation of temporal artery biopsy histology, so where biopsy findings are ambiguous (e.g. low-level inflammation restricted to the adventitia), discussion between the requesting clinician and the pathologist is desirable. In the absence of inflammatory infiltrate, a report of healed arteritis is not sufficient to diagnose GCA. Isolated vasa vasorum vasculitis is not diagnostic of GCA. Contralateral biopsy may slightly increase the yield of temporal artery biopsy, but is usually unnecessary. Biopsy may remain positive for several weeks after initiation of glucocorticoid therapy [79].

If neither vascular ultrasound nor biopsy is possible, and local MRI facilities and radiology support are available, then high-resolution 3T MRI of the cranial arteries could be used instead. In interpreting the results of these diagnostic tests, pretest probability (established on clinical grounds) should be taken into account (Fig. 1).

1. Strong recommendation: Patients with suspected GCA should have a confirmatory diagnostic test. This could be either a temporal artery biopsy at least 1 cm in length or an ultrasound of the temporal and axillary arteries, or both. QoE: +++. Consensus score: 9.33.

Which tests can be used to evaluate involvement of the aorta and its proximal branches in GCA? (PICO 2, 3)

One study (24 patients with suspected GCA, of whom 15 were diagnosed with GCA) compared FDG-PET with clinical diagnosis of GCA, giving a sensitivity of 67% (95% CI 38, 88) and a specificity of 100% (95% CI 66, 100) [80]. The QoE was ++; downgraded because of indirectness and publication bias.

One study (69 patients with suspected GCA/PMR, of whom 13 had biopsy evidence of GCA) compared vascular 18F-glucose uptake in the thorax and legs on FDG-PET with temporal artery biopsy, giving a sensitivity of 77% (95% CI 46, 95) and specificity of 66% (95% CI: 52%, 78%). Comparing vascular 18F-glucose uptake in the thorax on FDG-PET with temporal artery biopsy gave a sensitivity of 54% (95% CI 25, 81) and a specificity of 86% (95% CI 74,94). The QoE was +; downgraded because of risk of bias, indirectness and imprecision [81].

One study (24 patients with suspected GCA, of which 15 were diagnosed with GCA) compared CTA with clinical diagnosis of GCA, giving a sensitivity of 73% (95% CI 45, 92) and a specificity of 78% (95% CI 40, 97) [80]. The QoE was ++; downgraded for indirectness and publication bias. CTA can reveal wall thickening with contrast enhancement in biopsy-proven GCA [82]. There is also experience with CTA for accurate assessment of luminal diameter for large vessel stenosis in Takayasu arteritis [83].

No studies of magnetic resonance angiography (MRA) for the diagnosis of LV-GCA were found the met our criteria, but there is experience with MRI for the detection of vessel wall oedema reflective of inflammation and accurate assessment of luminal diameter for large vessel dilatation and stenosis in diseases of the major arteries, such as Takayasu arteritis. Gadolinium-enhanced MRA may help identify aortitis in the large vessel vasculitides, but appears to be very sensitive to glucocorticoid therapy [84].

In addition to showing inflammation of the large vessels, FDG-PET/CT may detect malignancy or infection and thus can be of use in the differential diagnosis of GCA. Contrast-enhanced CT of the chest and abdomen is also often used in clinical practice to screen for deep infection or occult malignancy. Moreover, aortic wall thickening on a contrast CT might help to identify GCA, albeit with lower sensitivity than FDG-PET/CT, and could also potentially have uses in settings where FDG-PET/CT is unavailable [80, 85, 86]. Additional advantages of FDG-PET and CT therefore include potential value in the workup of alternative diagnoses such as malignancy and infection.

As well as detecting axillary artery involvement for diagnosis of large vessel involvement in GCA, vascular ultrasound may also be able to visualize the carotid arteries and obtain more limited views of the subclavian arteries, vertebral arteries and parts of the aorta, but a higher level of operator expertise is required for these studies.

Overall, there is indirect evidence for the use of imaging tests to evaluate involvement of the aorta and its proximal branches in GCA, but the published evidence is extrapolated from other diseases such as Takayasu arteritis [77] and there is currently insufficient evidence from prospective studies of suspected GCA to yield precise estimates of diagnostic accuracy for these tests.

2. Conditional recommendation: 18F-FDG-PET, MRA, CTA or axillary artery ultrasound may be used to evaluate involvement of the aorta and its proximal branches. QoE: +. Consensus score: 9.36.

Recommendations for treatment of GCA

What is the best dose and route of initial glucocorticoid therapy for GCA in the absence of ischaemic visual manifestations? (PICO 1–3). There are no clinical trials comparing different initial oral glucocorticoid doses for GCA. However, clinical experience suggests that the vast majority of patients with GCA respond symptomatically within 1–7 days to a 40–60 mg daily dose of prednisolone, apart from irreversible sequelae such as established visual loss, stroke or tissue necrosis. Failure to respond to this dose should prompt re-evaluation of the diagnosis.

Downloaded from https://academic.oup.com/rheumatology/article/59/3/e1/5714024 by guest on 03 February 2023

In several clinical trials [87–89] the initial dose of oral prednisolone has been administered by weight rather than by a fixed dose, as is done for other systemic vasculitides in clinical practice. There was not enough direct evidence to be able to recommend dosing prednisolone strictly by weight, but nonetheless body weight (or at least size) remains a factor to be taken into account when deciding on an initial dose. Comorbidities also should be taken into account, since the toxicity of glucocorticoid therapy increases with the dose [49]. Clinicians should consider a higher dose within the 40–60 mg range for patients who have cranial ischaemic features of GCA such as ischaemic visual manifestations or jaw or tongue claudication, acknowledging that the evidence base for this is limited.

Two RCTs addressed the question of whether intravenous glucocorticoids should be given in patients with new-onset, uncomplicated GCA (i.e. those without any history of recent visual loss, amaurosis fugax or transient ischaemic attack): one was a single-centre, 78-week, double-blinded RCT ($n = 27$) and one was a 12-month open RCT ($n = 164$) [87, 90]. In the double-blinded RCT [90], patients received either 15 mg/kg body weight/day intravenous methylprednisolone for 3 days or placebo plus 40 mg/day oral prednisone. In the open RCT [87], the intervention group was treated with a single dose of 240 mg intravenous methylprednisolone followed by 0.7 mg/kg oral prednisone; one control group was treated with oral prednisone 0.7 mg/kg alone and a further control group was treated with a single dose of 240 mg intravenous methylprednisolone followed by 0.5 mg/kg oral prednisone. Due to the substantial differences in study design, efficacy outcomes were not meta-analysed. We pooled the data for treatment-related adverse events to increase the power to detect unwanted effects.

Moderate QoE (+++) from one study [90] suggested a reduction of the cumulative glucocorticoid dose at week 78 {median cumulative glucocorticoid dose 5636 mg [interquartile range (IQR) 4050–6690]} in the group that received 3 days of intravenous methylprednisolone compared with 7860 mg (IQR 7373–9005) in the control group. The glucocorticoid pulses were not counted for cumulative dose. In the other study, very low QoE (+) [87] indicated no benefit of pulse treatment at 1, 2, 6 and 12 months regarding cumulative glucocorticoid dose.

Low QoE (++) suggested that those in the methylprednisolone group had a higher probability of achieving remission while receiving $\leq$5 mg oral prednisone at three time points: week 36 [RR 4.64 (CI 1.24, 17.33)], week 52 [RR 5.11 (CI 1.39–18.81)] and week 78 [RR 2.57 (CI 1.12, 5.89)] [90].

No differences were found between pulse therapy and control groups as regards discontinuation of glucocorticoids at 12 months (QoE +) [87], patients with at least one relapse at 78 weeks and drug-free remission at 78 weeks (both with QoE ++) [90].

Comparing adverse events between treatment arms in these trials, no differences were observed between the intervention and control groups regarding infections, cushingoid habitus, psychiatric side effects, cardiovascular complications, diabetes, digestive disturbances, glucocorticoid-related ophthalmologic side effects, phlebitis/thrombosis, glucocorticoid-induced myopathy, abdominal bleeding, osteoporosis including fractures and mortality (all with QoE + or ++). Nonetheless, the small size of these two trials limits the power to show significant differences in adverse events between treatment arms.

In summary, there may possibly be a small benefit in terms of a reduced cumulative glucocorticoid dose in patients receiving glucocorticoid intravenous pulse therapy, but due to concerns over the likely increased risk of adverse effects with this therapy, the value of intravenous glucocorticoids in patients without acute or intermittent visual loss in GCA remains uncertain.

3. Conditional recommendation: The standard initial glucocorticoid dose for GCA is 40–60 mg oral prednis(ol)one per day. QoE: +. Consensus score: 9.44.

What is the best dose and route of initial glucocorticoid therapy for GCA in the presence of ischaemic visual manifestations? (PICO 4). Clinical trials have not been conducted in patients with acute ocular ischaemia, but observational data indicate that the vast majority of visual loss in GCA occurs before initiation of glucocorticoid therapy. Acute visual loss due to ocular ischaemia in GCA requires immediate action [29].

Intravenous glucocorticoid (methylprednisolone) therapy is used in systemic vasculitis for the treatment of life- or organ-threatening disease [91]. The intravenous formulation ensures rapid delivery of the drug to the site of action and, in addition, the very high doses required have rapid actions via non-genomic effects as well as on the genomic effects that take some hours to affect gene transcription [92, 93]. Intravenous glucocorticoid therapy is thus commonly used for patients with acute or intermittent visual loss due to GCA. If intravenous glucocorticoid therapy is not possible, 60–100 mg oral prednisolone may be given for up to 3 consecutive days.

4. Conditional recommendation: GCA patients with acute or intermittent visual loss may initially be given 500 mg–1 g intravenous methylprednisolone daily for up to 3 consecutive days before commencing oral prednis(ol)one therapy. If intravenous therapy is not immediately possible, this should not delay initiation of oral prednis(ol)one. QoE: +. Consensus score: 9.00.

How should glucocorticoid dose be tapered in GCA? (PICO 5). A single-centre, open, 2-month RCT compared different tapering regimens in 35 patients with new-onset GCA [94]. The same glucocorticoid dose was used in the first 5 days, but the rate of tapering thereafter differed between treatment groups. No significant difference was found between the groups at 2 months

Downloaded from https://academic.oup.com/rheumatology/article/59/3/e1/5714024 by guest on 03 February 2023

concerning relapse rate (QoE +) or visual loss (QoE ++).

In a multicentre RCT of tocilizumab as a glucocorticoid-sparing therapy for GCA [52], in two arms of the trial patients received placebo rather than tocilizumab. In one of these trial arms prednisone was tapered to zero over 6 months and in the other prednisone was tapered to zero over 12 months; relapses were treated at the discretion of the investigator. Patients with new-onset GCA receiving the 6 month prednisone taper without tocilizumab had a numerically higher frequency of relapse during the first year than receiving the 12 month prednisone taper, whereas the cumulative glucocorticoid dose was similar in these two trial arms. Although patients and investigators were blinded to the tapering regimen, this trial was not designed specifically to compare different prednisone tapering regimens.

5. Conditional recommendation: Glucocorticoid dose should be tapered to zero over 12–18 months, providing there is no return of GCA symptoms, signs or laboratory markers of inflammation. A more rapid dose reduction is appropriate for patients at high risk of glucocorticoid toxicity and/or those receiving concomitant glucocorticoid-sparing therapy. QoE: +. Consensus score: 8.81.

What dosing frequency of oral glucocorticoid should be used in GCA? (PICO 6, 7). A single-centre, open RCT with unclear length of follow-up compared the effects of 15 mg oral prednisone every 8 h with a single administration of 45 mg oral prednisolone/day. A third (alternate day) group received 90 mg oral prednisone every other day. Patients in all three groups were treated for the first 5 days with 20 mg oral prednisone every 8 h [95].

Remission and relapses at 4 weeks did not differ between groups of split-dose and single-dose prednisone treatment (QoE +). No difference was reported regarding hypercortisolism (which was not further defined), fractures, diabetes and glucocorticoid-induced myopathy (all with QoE +).

Comparing the single-daily and alternate-day treatment groups, at 4 weeks the single-daily group had higher remission rates at 4 weeks [RR 2.67 (CI 1.32, 5.39)] and lower relapse rates [RR 0.11 (CI 0.02, 0.80)] (QoE +). Hypercortisolism was more common in the single-daily group [RR 5.95 (CI 1.57, 22.57)]; fractures, diabetes and glucocorticoid-induced myopathy (all with QoE +) did not differ between groups.

This evidence, albeit low quality, raises concerns that alternate-day dosing may be associated with a higher relapse risk. Splitting the dose over the day does not seem to confer benefit and potentially carries risks of disturbance of diurnal rhythms, including sleep [96, 97]. In summary, in GCA there appears to be no reason to alter the standard guidance in other medical conditions to prescribe glucocorticoids as a single daily dose in the morning [12, 91].

6. Conditional recommendation: Patients should be prescribed a single daily dose of glucocorticoid rather than alternate day dosing or divided daily dosing. QoE: +. Consensus score: 9.53.

Should modified-release prednisone be used in place of standard therapy? (PICO 8). There was neither RCT data nor sufficient clinical experience to make any recommendation about modified-release prednisone in GCA.

7. No recommendation can be made for the use of modified-release prednisone in the treatment of GCA. QoE: insufficient evidence. Consensus score: 9.72.

When should further, non-biologic immunosuppression be added to glucocorticoid therapy for GCA? (PICO 9, 10). The effect of MTX has been investigated in three RCTs: a single-centre, 24-month, double-blinded RCT ($n = 42$) of patients with recent-onset GCA compared the addition of MTX 10 mg/week, *vs* placebo, to oral prednisone (initial prednisone dose of 60 mg/day) [98]. A multicentre, 12-month, double-blinded RCT ($n = 98$ instead of 300 originally planned) of patients with recent-onset GCA compared the addition of MTX 15 mg/week, *vs* placebo, to oral prednisone (initial prednisone dose of 1 mg/kg/day) [88]. A smaller single-centre, double-blinded RCT ($n = 21$) of patients with GCA whose prednisone dose had been reduced to 30 mg/day compared the adjunctive use of MTX 7.5 mg/week *vs* placebo; the initial glucocorticoid dose was at the discretion of the treating physician and some patients with visual symptoms received intravenous glucocorticoid pulse therapy [99].

Regarding efficacy data, the two larger trials [88, 98] could be pooled but the smallest trial [99] was considered separately because it substantially differed from the two other trials regarding design (lower MTX dose used, initiation of therapy upon reduction of glucocorticoid dose) and quality. Regarding adverse events, we combined the data from all three trials in order to increase the sensitivity to detect rare outcomes.

Pooling of the two larger studies indicated moderate QoE (+++) that MTX reduced the proportion with relapse at 12–24 months [RR 3.20 (95% CI 1.49, 6.87)] [88, 98]; the smallest trial showed no difference in relapse between the MTX and placebo groups (QoE +) [99]. In addition, the largest trial analysed 'treatment failure', defined as having two or more relapses or having a relapse that was not controlled by an increment of prednisone dose as scheduled: regarding this outcome, no difference was seen between the MTX and placebo groups (QoE ++) [88]. In none of the studies was a difference observed regarding cumulative glucocorticoid dose or the duration of glucocorticoid therapy (all outcomes with QoE + or ++); however, the largest trial reported only the median and IQR of the cumulative glucocorticoid dose rather than the mean and standard deviation, which reduced the validity of pooling the published data [88, 98, 99].

Downloaded from https://academic.oup.com/rheumatology/article/59/3/e1/5714024 by guest on 03 February 2023

Regarding possible modification of glucocorticoid-related adverse effects by MTX, mortality, vision loss, malignancy, infections, psychiatric side effects, fractures, cataracts, diabetes, hypertension, cushingoid habitus, weight gain and skin fragility did not differ between groups (data from one to three studies, all with QoE + or ++, except for hypertension, with QoE +++) [88, 98, 99].

Regarding possible MTX-related adverse effects, there was no strong evidence to support that MTX was associated either with a higher rate of withdrawal due to any side effect, nor an increase in individual side effects, including alanine aminotransferase/aspartate transaminase elevation, nausea/vomiting, thrombocytopenia, oral ulcers, alopecia, diarrhoea or gastric discomfort (QoE + or ++) [88, 98, 99]. Nonetheless, these trials were not designed nor powered to detect differences in adverse effects.

An individual patient data meta-analysis relating to these three RCTs was also identified [100] and included in this review because it is a more efficient use of the data than meta-analysis using published reports. According to the individual patient data meta-analysis, compared with the placebo group, the MTX group had a modest reduction of the risk of first and second relapse (HR 0.65, $P = 0.04$ and HR 0.49, $P = 0.02$, respectively), higher rates of glucocorticoid-free remission (HR 2.8, $P = 0.001$ for ≥24 weeks sustained discontinuation of glucocorticoids) and lower cumulative glucocorticoid doses (mean difference −1.1 g, $P = 0.007$ at week 96) [100].

In summary, the data from these three small RCTs indicate that there might be a modest benefit of MTX in GCA in reducing relapse and cumulative glucocorticoid dose and the data are encouraging regarding reducing the risk of second relapse as well as first relapse; however, overall the evidence remains equivocal. MTX has been used at doses of 7.5–15 mg weekly in clinical studies and up to 25 mg weekly orally or by subcutaneous injection in clinical practice.

A single-centre, 52-week, double-blinded RCT ($n = 31$) compared azathioprine 150 mg/day *vs* placebo in patients with PMR, with or without GCA, who required ≥5 mg daily oral prednisolone to control disease activity [101]. A lower daily glucocorticoid dose at the end of the follow-up (52 weeks) was found in the intervention group compared with the control group [mean dose difference 3 mg (CI 4.32, 0.28), QoE +]. Adverse events were similar in both groups (QoE +). Thirty-one patients were recruited, but only 18 reached the 52 week time point. According to the inclusion criteria for this trial, patients had to satisfy the Hazleman criteria for PMR. Eleven of 31 of these had a positive temporal artery biopsy. This trial did not truly fulfil the inclusion criteria for this review (at least 20 patients with GCA) and therefore no recommendation could be made on the basis of this trial. However, it is included here for completeness since it is frequently mentioned by narrative reviews.

Dapsone was studied at a dose of 50–100 mg/day in an open, multicentre RCT ($n = 47$) with an unclear length of follow-up [102]. A lower relapse risk was found in the treatment group compared with the control group [RR 0.37 (CI 0.16, 0.84), QoE +] and there was a trend towards a higher probability of glucocorticoid-free remission [RR 3.81 (CI 0.92, 15.81), QoE +] in the dapsone group. Anaemia was more common in the dapsone group compared with the control group [RR 8.89 (CI 1.27, 61.99), QoE ++] and the dapsone group had two cases of agranulocytosis. Rash, diabetes, bone complications, cardiovascular complications, infections and loss of vision did not differ between groups (all QoE +).

Two open RCTs of ciclosporin ($n = 82$) were published in the format of a letter [103, 104]. Ciclosporin was used at a daily dose of 2.0–3.5 mg/kg for 6 or 12 months. No benefit of the drug was observed regarding cumulative glucocorticoid dose, acute phase reactants or patients' and physicians' global assessments (all QoE +). However, there was an increased risk of treatment discontinuation due to toxicity [RR 13.00 (CI 1.78, 95.1), QoE ++].

The potential toxicity of dapsone or ciclosporin is likely to outweigh any possible benefit and their use is not recommended. There has been no RCT of leflunomide in GCA despite anecdotal evidence of benefit in case series and open, non-randomized studies [105–107]. In clinical practice, mycophenolate mofetil or cyclophosphamide have been occasionally used as immunosuppressive agents for severe GCA by analogy with their use in other systemic vasculitides, but they have not been formally studied in GCA.

8. Conditional recommendation: MTX might be considered for GCA, in combination with a glucocorticoid taper, in patients at high risk of glucocorticoid toxicity or who relapse. There is insufficient evidence to recommend any other oral immunosuppressive agent in GCA, including azathioprine, leflunomide or mycophenolate mofetil. QoE: ++. Consensus score: 8.92.

Which biologic agents can be used for GCA in addition to standard therapy? (PICO 11, 12). Tocilizumab was approved for GCA by US and European regulatory authorities in 2017 based on the results of two RCTs of addition of 1 year tocilizumab, or placebo, to tapering glucocorticoid therapy [52, 89].

In the larger of these trials [52], both patients with new GCA and patients with relapsing GCA were included. Patients with relapsing GCA had to have been treated for GCA no longer than 4 years prior to enrolment. Tocilizumab was combined with a standardized prednisone taper according to which prednisone cessation occurred at 6 months. Patients receiving placebo were treated with one of two alternative prednisone tapering schedules, by which prednisone cessation was achieved at either 6 months or 1 year if the patient remained relapse-free. If a patient relapsed during the study, prednisone therapy was escalated according to the investigator's discretion.

The primary endpoint (sustained remission at 1 year plus adherence to the tapering protocol, using a definition of remission incorporating CRP levels) was

Downloaded from https://academic.oup.com/rheumatology/article/59/3/e1/5714024 by guest on 03 February 2023

achieved in 56% of patients treated with weekly subcutaneous tocilizumab and in 53% of those treated every other week. In the placebo group, sustained remission at 1 year was achieved in 14% of those tapering prednisone over 6 months and 18% of those tapering prednisone over 1 year. Comparing weekly tocilizumab with placebo plus a 6 month glucocorticoid taper, the RR for sustained remission was 4.0 (95% CI 1.97, 8.12; QoE++++). Comparisons with other groups revealed similar results, with an RR of 3.01–3.79 (QoE ++++). Patients in the tocilizumab treatment arm also showed a higher rate of sustained remission using a modified definition of sustained remission that did not require CRP normalization [weekly tocilizumab compared with placebo plus a 6 month glucocorticoid taper: RR 2.95 (95% CI 1.66, 5.26), QoE +++; for other comparisons, RR 1.65–2.76, QoE+++].

In both this trial and in the smaller single-centre trial [89], an increase in relapse-free survival at 1 year [RR 3.57 (95% CI 2.29, 5.55), QoE ++++] was seen and a reduction in the 1 year cumulative glucocorticoid dose was observed in the tocilizumab treatment arms [mean difference −1434 mg (95% CI −2148, −720) in the weekly tocilizumab group compared with placebo plus 6 month tapering of glucocorticoids, QoE++++; mean difference from −1434 to −1956 mg in other comparisons, QoE++++]. Patient-reported outcomes were encouraging, although these were assessed using generic measures, since no disease-specific patient-reported outcome has yet been fully validated for GCA. Of note, although glucocorticoid-sparing efficacy was demonstrated, these studies were not designed or powered to demonstrate a reduction in glucocorticoid-related adverse events.

It has been argued that a glucocorticoid-sparing therapy such as tocilizumab would be more cost effective in the following GCA patient subgroups: first, GCA patients requiring escalation of glucocorticoid therapy due to relapse of disease, and second, GCA patients who are at high risk for adverse effects from further glucocorticoid treatment (e.g. on the basis of their comorbidity profile or other risk factors for glucocorticoid-related toxicity, including neuropsychiatric glucocorticoid-related adverse effects, previous fragility fractures or difficult-to-control diabetes mellitus).

UK prescribers should be aware that, at the time of writing, a limited duration of tocilizumab therapy for GCA has been approved by the Scottish Medicines Consortium and by NHS England for defined patient groups, taking into account cost-effectiveness data available at the time of the technology appraisal.

Tocilizumab has only been approved for weekly subcutaneous use, although it has also been studied in intravenous formulations [89]. In a multicentre RCT [52], one of the treatment arms received subcutaneous tocilizumab every 2 weeks rather than weekly; patients in this treatment arm also reached the primary endpoint, although it appeared to be less efficacious in relapsing patients. The trials in GCA have not demonstrated an increased risk of adverse events with tocilizumab [52, 89]; pooling of data from both trials indicated a lower rate of serious adverse events in patients treated with tocilizumab than those treated with placebo [RR 0.64 (95% CI 0.41, 1.00), QoE+++].

Abatacept was studied in a single, small trial [108]. All patients received abatacept initially in addition to glucocorticoid therapy. Those achieving remission were randomized in week 12 to either continue the drug or to switch to placebo. Time-to-relapse analysis, which was the primary endpoint, significantly favoured abatacept. A post hoc analysis to compare the proportion of patients in remission at 12 months did not show a significant difference between the treatment arms [RR 1.50 (CI 0.71, 3.17), QoE ++], likely due to the small size of the study. At present, abatacept is not approved for treatment of GCA.

TNF inhibitors have been studied in two RCTs [109, 110], both of which showed inefficacy but an increased incidence of infections. A third, small RCT of etanercept for GCA [111] did not fulfil the inclusion criteria for the literature review. Although it showed a lower cumulative glucocorticoid dose in the etanercept arm, this trial failed to show a significant result for its primary outcome. Based on this evidence, TNF inhibitors cannot be recommended for GCA.

9. Strong recommendation: Tocilizumab can be considered for GCA, in combination with a glucocorticoid taper, especially in patients at high risk of glucocorticoid toxicity or who relapse. TNF inhibitors are not recommended in GCA. QoE: +++. Consensus score: 9.61.

Should anticoagulant or antiplatelet agents be given for GCA? (PICO 12–15). No RCTs relating to aspirin or other anticoagulant/antiplatelet agents were found. A Cochrane review found no evidence from RCTs to determine the safety and efficacy of low-dose aspirin as an adjunctive treatment in GCA [112]. National and society guidelines for the secondary prevention of coronary and other atherosclerotic vascular diseases should be followed.

10. The routine use of antiplatelet or anticoagulant agents for GCA is not recommended. QoE: insufficient evidence. Consensus score: 9.28.

Should cholesterol-lowering agents be given for GCA? (PICO 16). No RCTs of cholesterol-lowering agents for GCA were found. National and society guidelines for the secondary prevention of coronary and other atherosclerotic vascular diseases should be followed.

11. The routine use of cholesterol-lowering agents such as statins for GCA is not recommended. QoE: insufficient evidence. Consensus score: 9.53.

Applicability and utility

This guideline represents a framework upon which clinical practice should be based. However, as with any guideline, individual patient circumstances can have important influences on clinical decision making and clinicians should continue to work alongside patients to make shared decisions about care. Failure to adhere to this guideline should not necessarily be considered

Downloaded from https://academic.oup.com/rheumatology/article/59/3/e1/5714024 by guest on 03 February 2023

negligent, nor should adherence to these recommendations constitute a defence against a claim of negligence.

Potential organizational barriers to implementation

In practice, constraints of the healthcare system may create challenges to widespread implementation of this guideline. For example, implementing rapid-access vascular ultrasound as a diagnostic test in GCA is dependent not only on local expertise and experience in the technique itself, but also on the entire care pathway for patients with suspected GCA, including appropriate, timely referrals and clinical expertise such that the results of the test can be interpreted appropriately.

As another example, follow-up every 2–8 weeks for the first 6 months (less frequently thereafter) may seem ambitious, but this could be delivered via a shared care model in collaboration with primary care by which the patient and general practitioner receive the information and support they need and have ready access to secondary care if need be. Nonetheless, it is also recognized that specific quality standards are necessary to drive clinical improvement.

Cost and cost-effectiveness implications for implementation

A formal health economic evaluation was not conducted as part of the guideline development process.

The use of additional imaging tests could incur healthcare costs. This has to be set against the advantages of accurate, timely diagnosis of GCA, in particular the potential cost savings of avoiding unnecessary treatment of patients without the disease.

A UK National Institute for Health and Care Excellence (NICE) technology appraisal has been conducted with regard to tocilizumab therapy for GCA [113], which has the potential to significantly increase the direct costs of drug treatment of GCA. Both biologic and non-biologic therapies used alongside glucocorticoid treatment would incur additional costs due to the requirements for regular blood monitoring. However, this must be set against the potential cost savings arising from a reduction in cumulative glucocorticoid doses and thereby a reduction in glucocorticoid-associated adverse events. On the basis of overall cost-effectiveness data, approval was granted by NHS England and the Scottish Medicines Consortium for tocilizumab treatment for defined GCA patient groups; readers are directed to the appropriate guidance for a more detailed explanation.

Mechanism for auditing compliance with the guideline

Quality standards have been defined based on the fundamentals of good clinical care, as outlined in the general principles. Audit should be performed on an unbiased (e.g. consecutive) sample of patients presenting to a clinic or service. A draft audit tool that may be adapted for local use is published as Fig.

Statement of contribution of the literature review team

Christian Dejaco led the SLR team. The literature review team was split into three groups, each group consisting of three members: group 1 (Duftner, Mackie, Appenzeller) performed the SLR on diagnostic tests/strategies, group 2 (Dejaco, Camellino, Hutchings) performed the SLR on therapeutic interventions and group 3 (Mahr, Gonzalez-Chiappe, Wagner Silva de Souza) performed the SLR on prognostic factors. Two members of each group independently performed screening, inclusion/exclusion of articles, data extraction and quality appraisal. Results were compared between the two members and any discordance was resolved by discussion, then consulting the third member of the group where no consensus could be reached. Christian Dejaco supervised the progress of the SLR in each group and the preparation of the evidence tables. The searches underpinning the 2018 update to the SLR were conducted by Gary Reynolds, who also worked with the literature review team in the appraisal of new evidence.

Individuals who contributed to the guideline development but did not participate in the final voting are listed below and their contributions are gratefully acknowledged:

Niral Karia, ophthalmologist, Southend University Hospital, Southend, UK

Kevin Barraclough, general practitioner, Hoyland House General Practice, Painswick, UK

Eric Clark, patient

Mavis Smith, patient (PMR and GCA North East)

Andrew Hutchings, statistician, London School of Hygiene and Tropical Medicine, London, UK

Presentation and dissemination of final guidelines

The final guidelines will be disseminated by publication in the journal Rheumatology (Oxford) as well as by uploading onto the BSR homepage.

Funding: The British Society for Rheumatology provided financial support for this guideline.

Disclosure statement: Christian Dejaco – received consultancy fees and honoraries from Roche, Sanofi, AbbVie, MSD, Pfizer, UCB, Bristol-Myers Squibb; first author of EULAR imaging recommendations in large vessel vasculitis, first author of ACR/EULAR recommendations for management of PMR, co-author of management recommendations for large vessel vasculitis.

Simone Appenzeller – none.

Dario Camellino – received travel expenses, consultancy fees and speaker fees from AbbVie, Celgene, Janssen-Cilag, Eli Lilly, Mylan and Sanofi.

Christina Duftner – none.

Solange Gonzalez-Chiappe – none.

Alfred Mahr – received honoraria for advisory board meetings and lectures from Chugai Pharma France.

Chetan Mukhtyar – none.

Gary Reynolds – none.

Alexandre Wagner Silva de Souza – none.

Elisabeth Brouwer – an employee of the University Medical Center Groningen, Groningen, The Netherlands. Part of the work is funded by Reuma Nederland, lead author in the development of local and national guidelines for GCA in The Netherlands.

Marwan Bukhari – involved in the GCA Consortium, which is indirectly funded by Roche/Chugai, and virtual advisory board member for Roche/Chugai on GCA.

Frank Buttgereit – received consultancy fees, honoraria and/or travel expenses from Horizon Pharma, Mundipharma, Roche and Pfizer and grant/study support from Horizon Pharma and Mundipharma.

Dorothy Byrne – vice chair of PMRGCAuk.

Maria C. Cid – received a research grant from Kiniksa and consulting fees from AbbVie and Janssen, participated in clinical trials sponsored by GlaxoSmithKline and Kiniksa and co-author in publications of work sponsored by Roche.

Marco Cimmino – none.

Haner Direskeneli – local advisory board member for Roche for GCA.

Kate Gilbert – representative of PMRGCAuk.

Tanaz A. Kermani – received consultancy fees from AbbVie in March 2018.

Asad Khan – received speaker fees from Chugai.

Peter Lanyon – former president of the BSR (April 2016–18) and chair of the Rare Autoimmune Rheumatic Disease Alliance (RAIRDA).

Raashid Luqmani – received grants, honoraria and travel support for EULAR 2019 from Roche/Chugai.

Christian Mallen – none.

Justin C. Mason – received speaker fees and consultancy fees from Roche/Chugai.

Eric L. Matteson – none.

Peter A. Merkel – received consulting fees from AbbVie, AstraZeneca, Biogen, Boeringher-Ingelheim, Bristol-Myers Squibb, Celgene, ChemoCentryx, CSL Behring, Genentech/Roche, Genzyme/Sanofi,

Downloaded from https://academic.oup.com/rheumatology/article/59/3/e1/5714024 by guest on 03 February 2023

GlaxoSmithKline, InflaRx, Insmed, Janssen and Kiniksa and research support from Bristol-Myers Squibb and Genentech/Roche/Chugai.

Susan Mollan – advisory board member and received speaker fees from Roche/Chugai, representative of the Royal College of Ophthalmologists, co-author of the EULAR GCA guideline group and co-author of the European Headache Federation GCA guideline group.

Lorna Neil – chair of PMR-GCA Scotland and patient representative for the EULAR working group on imaging in LVV.

Eoin O'Sullivan – none.

Maria Sandovici – none.

Wolfgang A. Schmidt – received consulting fees from GlaxoSmithKline, Novartis, Roche and Sanofi; member of the speaker's bureau for Chugai, GlaxoSmithKline, Novartis, Roche and Sanofi and participated in trials/studies for GlaxoSmithKline, Novartis, Roche and Sanofi.

Richard Watts – none.

Madeline Whitlock – none.

Elaine Yacyshyn – none.

Steven Ytterberg – none.

Bhaskar Dasgupta – received consultancy fees for membership on clinical trials advisory boards and for developing trial protocols; speaker fees from Roche-Chugai, Sanofi, ERT, Bristol-Myers Squibb, GlaxoSmithKline and AbbVie and ultrasound workshop/GCA symposium grants to Southend University Hospital; honorary president of PMRGCAuk; television appearance on BBC2 health program 'Trust me, I'm a doctor', released February 2017.

Sarah Mackie – patron of PMRGCAuk, founding member of the TARGET Research Consortium, co-chair of the OMERACT PMR Working Group, member of the OMERACT Vasculitis Working Group, subinvestigator for the licensing RCT of tocilizumab for giant cell arteritis (GiACTA; site principal investigator) and for sirukumab for giant cell arteritis (SIRRESTA; local principal investigator) and UK clinical investigator for an international multicentre industry-sponsored trial of sarilumab for GCA and attendance at EULAR 2019 supported by Roche/Chugai.

Disclaimer: The views expressed are those of the authors and not necessarily those of the National Institute for Health Research or the UK Department of Health and Social Care.

Supplementary data

Supplementary data are available at *Rheumatology* online.

BSR and BHPR guidelines for the management of polymyalgia rheumatica

Bhaskar Dasgupta[1], Frances A. Borg[1], Nada Hassan[1], Kevin Barraclough[2], Brian Bourke[3], Joan Fulcher[4], Jane Hollywood[1], Andrew Hutchings[5], Valerie Kyle[6], Jennifer Nott[7], Michael Power[8] and Ash Samanta[9] on behalf of the BSR and BHPR Standards, Guidelines and Audit Working Group

Key words: Guidelines, Polymyalgia rheumatica, Diagnosis, Treatment, Corticosteroid.

Executive summary

Scope and purpose

PMR is the most common inflammatory rheumatic disease in the elderly and is one of the biggest indications for long-term steroid therapy. There are difficulties in diagnosis, with heterogeneity in presentation, response to steroids and disease course.

The aim of these guidelines is a safe and specific diagnostic process for PMR, using continued assessment, and discouragement of hasty initial treatment. Their scope is to provide advice for the diagnosis of PMR, management and monitoring of disease activity, complications and relapse. The management of GCA is not covered and is published separately.

The full guideline is available at *Rheumatology* online.

Guidelines

(1) We recommend that a safe, stepped diagnostic process be adopted for the evaluation of PMR (Strength of recommendation C).

Diagnosis of PMR should start with evaluation of core inclusion and exclusion criteria, followed by assessment of the response to a standardized dose of steroid [1]. Atypical features or response to steroid should prompt consideration of alternative pathology, and specialist referral.

Unlike with GCA, urgent institution of steroid therapy is not necessary and can be delayed to allow full assessment. However, if the patient does present with symptoms suspicious of GCA, then urgent institution of high-dose steroid therapy is needed (see Guidelines for Management of GCA).

(i) Core inclusion criteria:

- Age >50 years, duration >2 weeks
- Bilateral shoulder or pelvic girdle aching, or both
- Morning stiffness duration of >45 min
- Evidence of an acute-phase response

PMR can be diagnosed with normal inflammatory markers, if there is a classic clinical picture and response to steroids. These patients should be referred for specialist assessment.

Downloaded from https://academic.oup.com/rheumatology/article/49/1/186/1787... by guest on 03 February 2023

(ii) Core exclusion criteria:

- Active infection
- Active cancer
- Active GCA (see part iii)

The presence of the following conditions decreases the probability of PMR, and they should also be excluded:

- Other inflammatory rheumatic diseases
- Drug-induced myalgia
- Chronic pain syndromes
- Endocrine disease
- Neurological conditions, e.g. Parkinsons disease

(iii) Patients should be assessed for evidence of GCA, as this requires urgent institution of high-dose steroid (see separate guidelines)

- Abrupt-onset headache (usually temporal) and temporal tenderness
- Visual disturbance, including diplopia
- Jaw or tongue claudication
- Prominence, beading or diminished pulse on examination of the temporal artery
- Upper cranial nerve palsies
- Limb claudication or other evidence of large-vessel involvement

(iv) Patients should be assessed for response to an initial standardized dose of prednisolone 15 mg daily orally [1, 2].

A patient-reported global improvement of $\geqslant$70% within a week of commencing steroids is consistent with PMR, with normalization of inflammatory markers in 4 weeks. A lesser response should prompt the search for an alternative condition.

(v) The diagnosis of PMR should be confirmed on further follow-up [2]. Follow-up visits should include vigilance for mimicking conditions.

(2) We recommend documentation in the patient's medical record of a minimum data set, which forms the basis for the diagnosis.

- The core clinical inclusion and any exclusion criteria
- Laboratory investigations before commencement of steroid therapy
  - Full blood count
  - ESR/plasma viscosity and/or CRP
  - Urea and electrolytes
  - Liver function tests
  - Bone profile
  - Protein electrophoresis (also consider urinary Bence Jones Protein)
  - Thyroid stimulating hormone
  - Creatine kinase
  - RF (ANA and anti-CCP antibodies may be considered)
  - Dipstick urinalysis
  - Chest X-ray may be required

(3) We recommend the following approach for the evaluation of proximal pain and stiffness [3] (Fig. 1).

(4) We recommend early specialist referral in the following circumstances (C).

Atypical features or features that increase likelihood of a non-PMR diagnosis:

- Age <60 years
- Chronic onset (>2 months)
- Lack of shoulder involvement
- Lack of inflammatory stiffness
- Prominent systemic features, weight loss, night pain, neurological signs
- Features of other rheumatic disease
- Normal or extremely high acute-phase response

Treatment dilemmas such as:

- Incomplete, poorly sustained or non-response to corticosteroids
- Inability to reduce corticosteroids
- Contraindications to corticosteroid therapy
- The need for prolonged corticosteroid therapy (>2 years)

However, patients with a typical clinical picture and complete sustained response to treatment, and no adverse events can be managed in primary care.

(5) We recommend initiation of low-dose steroid therapy with gradually tailored tapering in straightforward PMR (B).

In the absence of GCA, urgent steroid therapy is not indicated before the clinical evaluation is complete.

The suggested regimen is:

- Daily prednisolone 15 mg for 3 weeks
- Then 12.5 mg for 3 weeks
- Then 10 mg for 4–6 weeks
- Then reduction by 1 mg every 4–8 weeks or alternate day reductions (e.g. 10/7.5 mg alternate days, etc.)

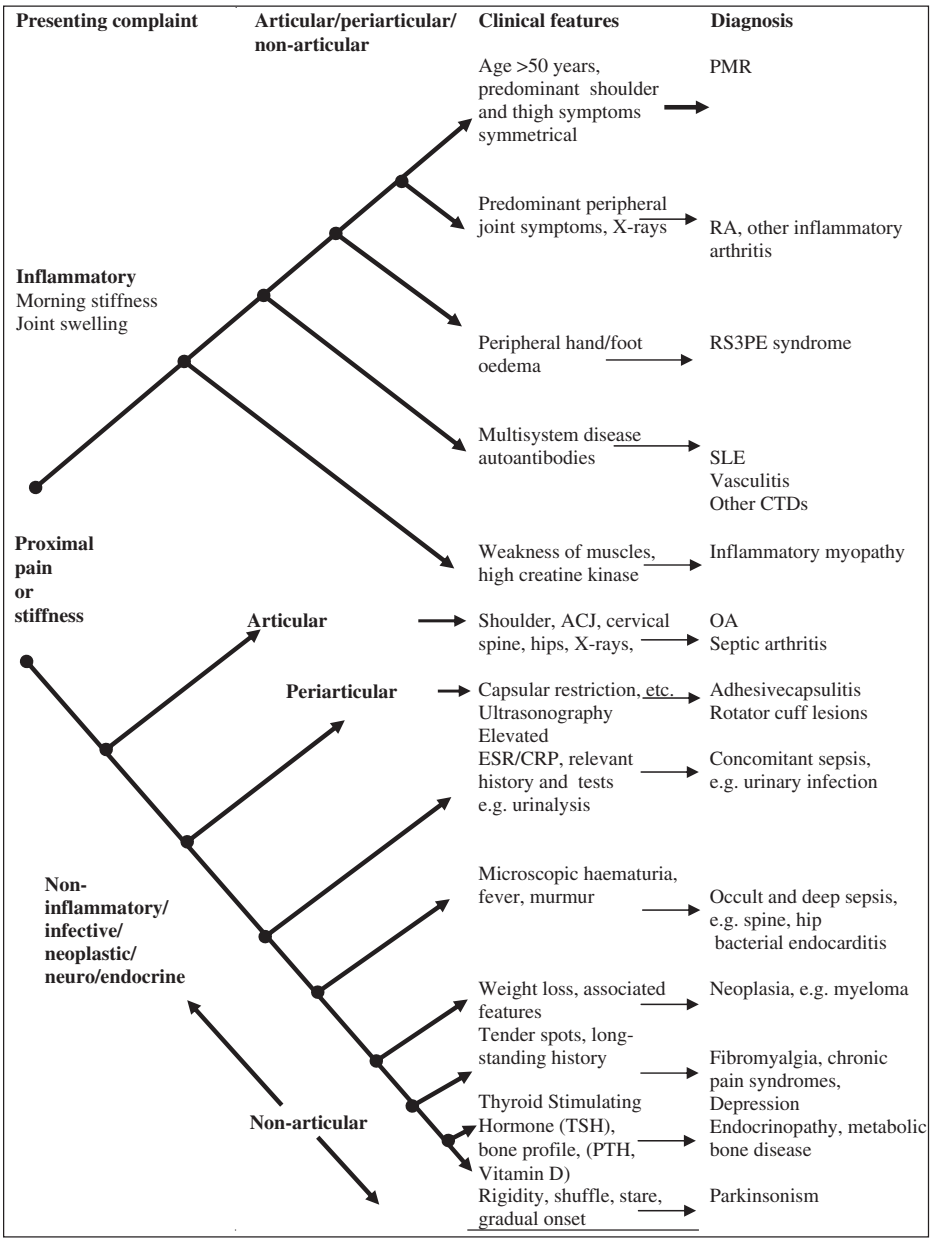
However, there is no consistent evidence for an ideal steroid regimen suitable for all patients. Therefore, the approach to treatment must be flexible and tailored to the individual as there is heterogeneity in disease course. Some benefit from a more gradual steroid taper. Dose adjustment may be required for disease severity, comorbidity, side effects and patient wishes.

Intramuscular methylprednisolone (i.m. depomedrone) may be used in milder cases and may reduce the risk of steroid-related complications. Initial dose is 120 mg every 3–4 weeks, reducing by 20 mg every 2–3 months [4].

Usually 1–2 years of treatment is needed [5]. The need for ongoing therapy after 2 years of treatment should prompt the consideration of an alternative diagnosis, and referral for specialist evaluation.

Downloaded from https://academic.oup.com/rheumatology/article/49/1/186/1789113 by guest on 03 February 2023

FIG. 1 Approach to the evaluation of proximal pain and stiffness. ACJ: acromio-clavicular joint.



(6) We recommend the use of bone protection when initiating steroids for PMR to prevent the complications of osteoporosis (A−).

- Individuals with high fracture risk, e.g. aged ⩾65 years or prior fragility fracture
  - Bisphosphonate with calcium and vitamin D supplementation
  - DEXA not required
- Other individuals
  - Calcium and vitamin D supplementation when starting steroid therapy.
  - DEXA scan recommended
  - A bone-sparing agent may be indicated if *T*-score is −1.5 or lower.
- Individuals requiring higher initial steroid dose
  - Bisphosphonate with calcium and vitamin D supplementation (because higher cumulative steroid dose is likely)

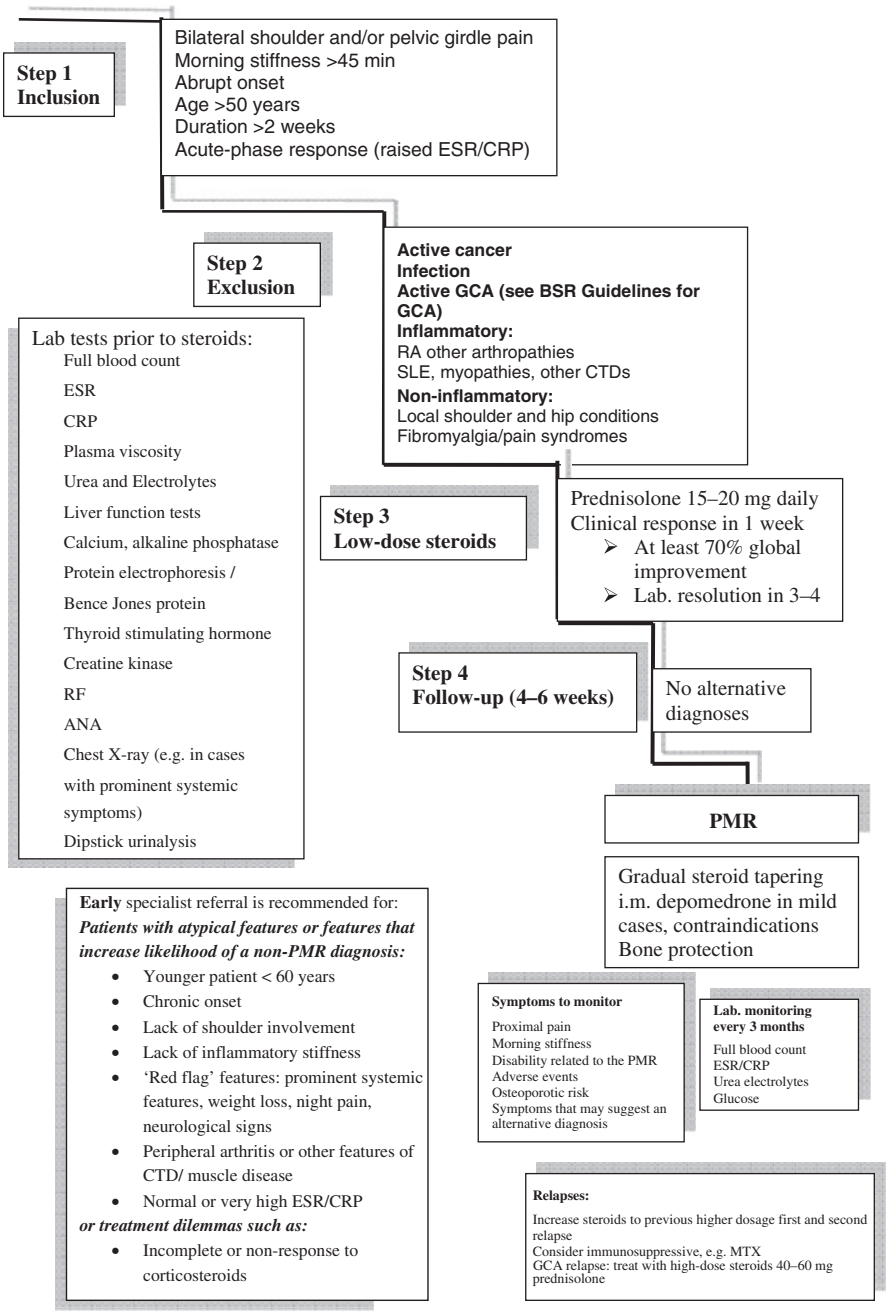
(7) We recommend vigilant monitoring of patients for response to treatment and disease activity (B).

Follow-up schedule:

Weeks 0, 1–3, 6, Months 3, 6, 9, 12 in first year (with extra visits for relapses or adverse events).

Downloaded from https://academic.oup.com/rheumatology/article/49/1/186/1789113 by guest on 03 February 2023

FIG. 2 Approach to diagnosis and management of polymyalgia.



Early follow-up is necessary as part of the diagnosis to evaluate response to initial therapy [2], and the first follow-up should occur at 1–3 weeks before commencement of steroids.

Clinical assessment:

At each visit, patients should be assessed for the following:

- Response to treatment: proximal pain, fatigue and morning stiffness

It is important to distinguish between symptoms due to inflammation and those due to co-existing degenerative problems.

- Complications of disease including symptoms of GCA, e.g. headaches, jaw claudication and large-vessel disease
- Steroid-related adverse events
- Atypical features or those suggesting an alternative diagnosis

Downloaded from https://academic.oup.com/rheumatology/article/49/1/186/1789113 by guest on 03 February 2023

Laboratory monitoring:

- Full blood count, ESR/CRP, urea and electrolytes, glucose

Duration of treatment and follow-up:

- Usually 1–3 years of treatment, although some will require small doses of steroids beyond this. Flexibility in approach is necessary given the heterogeneous nature of disease. Steroids may be stopped when the patient is asymptomatic from their inflammatory symptoms.
- Isolated raised ESR or CRP is not an indication for continuing steroid therapy but may require investigation and referral.
- Persistent pain may arise from co-existing OA and rotator cuff tears.

(8) We recommend the following approach to relapse of disease.

Relapse is the recurrence of symptoms of PMR or onset of GCA, and not just unexplained raised ESR or CRP [6].

Treatment of relapse:

- Clinical features of GCA: treat as GCA (usually oral prednisolone 40–60 mg daily) (see GCA guideline)
- Clinical features of PMR: increase prednisolone to previous higher dose.
- Single i.m. injection of methylprednisolone (depomedrone) 120 mg can also be used.
- Further relapses: consider introducing DMARD therapy after two relapses

The approach to diagnosis and management of PMR is summarized in Fig. 2.

Patient education

An ARC patient information booklet is available. Further support is available from local patient groups under the auspices of PMRGCA-UK.

Recommendations for audit

Audit standards should include the minimum data set recorded prior to steroid therapy, initial steroid dose and taper, monitoring schedule, use of bone protection and provision of patient information.

Outcomes measures include disease relapse, persistent disease activity, cumulative steroid dosage, adverse events and complications of therapy and quality of life.

Disclosure statement: The authors have declared no conflicts of interest.

Guidelines and recommendations developed and/or endorsed by the American College of Rheumatology (ACR) are intended to provide guidance for particular patterns of practice and not to dictate the care of a particular patient. The ACR considers adherence to the recommendations within this guideline to be voluntary, with the ultimate determination regarding their application to be made by the physician in light of each patient's individual circumstances. Guidelines and recommendations are intended to promote beneficial or desirable outcomes but cannot guarantee any specific outcome. Guidelines and recommendations developed and endorsed by the ACR are subject to periodic revision as warranted by the evolution of medical knowledge, technology, and practice. ACR recommendations are not intended to dictate payment or insurance decisions, and drug formularies or other third-party analyses that cite ACR guidelines should state this. These recommendations cannot adequately convey all uncertainties and nuances of patient care.

The American College of Rheumatology is an independent, professional, medical and scientific society that does not guarantee, warrant, or endorse any commercial product or service.

Objective. To provide evidence-based recommendations and expert guidance for the management of giant cell arteritis (GCA) and Takayasu arteritis (TAK) as exemplars of large vessel vasculitis.

Methods. Clinical questions regarding diagnostic testing, treatment, and management were developed in the population, intervention, comparator, and outcome (PICO) format for GCA and TAK (27 for GCA, 27 for TAK). Systematic literature reviews were conducted for each PICO question. The Grading of Recommendations Assessment, Development and Evaluation methodology was used to rate the quality of the evidence. Recommendations were developed by the Voting Panel, comprising adult and pediatric rheumatologists and patients. Each recommendation required ≥70% consensus among the Voting Panel.

Results. We present 22 recommendations and 2 ungraded position statements for GCA, and 20 recommendations and 1 ungraded position statement for TAK. These recommendations and statements address clinical questions relating to the use of diagnostic testing, including imaging, treatments, and surgical interventions in GCA and TAK. Recommendations for GCA include support for the use of glucocorticoid-sparing immunosuppressive agents and the use of imaging to identify large vessel involvement. Recommendations for TAK include the use of nonglucocorticoid immunosuppressive agents with glucocorticoids as initial therapy. There were only 2 strong recommendations; the remaining recommendations were conditional due to the low quality of evidence available for most PICO questions.

Conclusion. These recommendations provide guidance regarding the evaluation and management of patients with GCA and TAK, including diagnostic strategies, use of pharmacologic agents, and surgical interventions.

INTRODUCTION

Giant cell arteritis (GCA) and Takayasu arteritis (TAK) are systemic vasculitides that primarily affect large- and medium-sized vessels (1). GCA can present with both cranial and extracranial manifestations. Cranial manifestations include headaches, scalp tenderness, vision loss, and jaw claudication. Large vessel ("extracranial") involvement results in arterial stenosis and aneurysms, causing absent pulses and limb claudication (2). GCA is more common in individuals of Northern European descent who are older than 50 years of age. Diagnosis is based on clinical presentation, pathologic abnormalities on temporal artery biopsy, and/or evidence of large vessel involvement on vascular imaging (1–6). Glucocorticoids are the mainstay treatment for GCA, but tocilizumab has been approved by the US Food and Drug Administration for the treatment of GCA (7,8).

TAK causes granulomatous inflammation of the aorta and its branches. It is more common in younger women (9,10). Clinical manifestations include constitutional symptoms, elevated levels of inflammation markers, and arterial stenosis and/or aneurysms resulting in limb claudication and absent pulses (11). Treatment options include glucocorticoids, nonglucocorticoid immunosuppressive agents, and surgical management of vascular abnormalities (12).

As GCA and TAK share clinical manifestations, similar questions arise regarding their treatment and management. Recent studies have broadened treatment options for GCA, and vascular imaging is increasingly used for diagnosis and management. This guideline was developed to provide evidence-based recommendations for the evaluation and management of GCA and TAK.

METHODS

This guideline followed the American College of Rheumatology (ACR) guideline development process (https://www.rheumatology.org/Practice-Quality/Clinical-Support/Clinical-Practice-Guidelines) using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) methodology to rate the quality of evidence and develop recommendations (13–15). ACR policy guided the management of conflicts of interest and disclosures (https://www.rheumatology.org/Practice-Quality/Clinical-Support/Clinical-Practice-Guidelines/Vasculitis). Supplementary Appendix 1 (available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24632/abstract) presents a detailed description of the methods. Briefly, the Literature Review team undertook systematic literature reviews for predetermined questions specifying the clinical population, intervention, comparator, and outcomes (PICO). An in-person Patient Panel of 11 individuals with different types of vasculitis (3 patients with GCA or TAK) was moderated by a member of the Literature Review team (ABD). This Patient Panel reviewed the evidence report (along with a summary and interpretation by the moderator) and provided patient perspectives and preferences about their personal experiences regarding clinical and treatment aspects of their disease. The Voting Panel comprised 9 adult rheumatologists, 5 pediatric rheumatologists, and 2 patients; they reviewed the Literature Review team's evidence summaries and, bearing in mind the Patient Panel's deliberations, formulated and voted on recommendations. A recommendation required ≥70% consensus among the Voting Panel.

The article is published simultaneously in *Arthritis & Rheumatology*.

How to interpret the recommendations

A *strong* recommendation is typically supported by moderate- to high-quality evidence (e.g., multiple randomized controlled trials). For a strong recommendation, the recommended course of action would apply to all or almost all patients. Only a small proportion of clinicians/patients would not want to follow the recommendation. In rare instances, a strong recommendation may be based on very low– to low-certainty evidence. For example, an intervention may be strongly recommended if it is considered low-cost, without harms, and the consequence of not performing the intervention may be catastrophic. An intervention may be strongly recommended against if there is high certainty that the intervention will lead to more harm than the comparison with very low or low certainty about its benefit (16).

A *conditional* recommendation is generally supported by lower-quality evidence or a close balance between desirable and undesirable outcomes. For a conditional recommendation, the recommended course of action would apply to the majority of the patients, but the alternative is a reasonable consideration. Conditional recommendations always warrant a shared decision-making approach. We specify conditions under which the alternative may be considered.

In some instances, the committee found that the evidence for a particular PICO question did not support a graded recommendation or did not favor one intervention over another. However, the Voting Panel believed that the PICO question addressed a commonly encountered clinical question which has not been fully clarified and requires further investigation, and thus felt that providing guidance for this question was warranted. For these situations, we present "ungraded position statements," which reflect general views of the Voting Panel.

In this evidence-based guideline, we explicitly used the best evidence available and present that in a transparent manner for the clinician reader/user (10). In some instances, this includes randomized trials in which the interventions under consideration are directly compared. The GRADE system rates evidence that comes exclusively from the collective experience of the Voting Panel and Patient Panel members as "very low–quality" evidence (15).

For each recommendation, details regarding the PICO questions and the GRADE evidence tables can be found in Supplementary Appendix 2 (http://onlinelibrary.wiley.com/doi/10.1002/acr.24632/abstract).

RESULTS

For the GCA evidence report, 399 articles were reviewed to address 27 PICO questions. For the TAK evidence report, 347 articles were reviewed to address 27 PICO questions.

Table 1. Definitions of selected terms used in the recommendations and ungraded position statements for GCA and TAK*

Term	Definition
Disease states	
Suspected disease	Clinical signs and/or symptoms suggestive of GCA/TAK and not explained by other conditions
Active disease	New, persistent, or worsening clinical signs and/or symptoms attributed to GCA/TAK and not related to prior damage
Severe disease	Vasculitis with life- or organ-threatening manifestations (e.g., vision loss, cerebrovascular ischemia, cardiac ischemia, limb ischemia)
Nonsevere disease	Vasculitis without life- or organ-threatening manifestations (e.g., constitutional symptoms, headache, jaw claudication, symptoms of polymyalgia rheumatica)
Remission	Absence of clinical signs or symptoms attributed to active GCA/TAK, on or off immunosuppressive therapy
Refractory disease	Persistent active disease despite an appropriate course of immunosuppressive therapy
Relapse	Recurrence of active disease following a period of remission
Cranial ischemia	Visual and neurologic involvement including amaurosis fugax, vision loss, and stroke
Treatments	
IV pulse GCs	IV methylprednisolone 500–1,000 mg/day (adults) or 30 mg/kg/day (children; maximum 1,000 mg/day) or equivalent for 3–5 days
High-dose oral GCs	Prednisone 1 mg/kg/day up to 80 mg or equivalent
Moderate-dose oral GCs	Prednisone 0.5 mg/kg/day (generally 10–40 mg/day in adults) or equivalent
Low-dose oral GCs	Prednisone ≤10 mg/day or equivalent
Non-GC nonbiologic immunosuppressive therapy	Azathioprine, leflunomide, methotrexate, mycophenolate mofetil, cyclophosphamide
Biologics	Abatacept, tumor necrosis factor inhibitor, tocilizumab
Surgical intervention	Angioplasty, stent placement, vascular bypass, vascular graft
Disease assessments	
Clinical monitoring	Assessing for clinical signs and symptoms of active disease, obtaining 4 extremity blood pressures, and obtaining clinical laboratory results, including inflammation marker levels
Inflammation markers	Erythrocyte sedimentation rate, C-reactive protein level
Noninvasive imaging	Computed tomography angiogram, magnetic resonance angiogram, positron emission tomography scan, vascular ultrasound, magnetic resonance imaging of temporal and scalp arteries
Invasive imaging	Conventional catheter-based angiogram

* GCA = giant cell arteritis; TAK = Takayasu arteritis; IV = intravenous; GCs = glucocorticoids.

Recommendations and ungraded position statements for the management of GCA

Table 1 presents definitions of selected terms used in the recommendations, including disease states such as severe disease, dosing ranges for glucocorticoids, categorization of medications, and disease assessments. Tables 2 and 3 present the recommendations with their supporting PICO questions and levels of evidence. We present 22 recommendations and 2 ungraded position statements for GCA. All but 1 of the recommendations are conditional due to very low– to low-quality evidence. Figure 1 presents key recommendations for the treatment of GCA.

Diagnostic testing

Recommendation: For patients with suspected GCA, we conditionally recommend an initial unilateral temporal artery biopsy over bilateral biopsies.

Initially, a unilateral biopsy is recommended. However, bilateral temporal artery biopsies may be appropriate if the symptoms are not clearly localized to 1 temporal artery. Proceeding with the contralateral biopsy is also appropriate if the unilateral biopsy result is negative and additional evidence for cranial GCA is sought (17).

Recommendation: For patients with suspected GCA, we conditionally recommend a long-segment temporal artery biopsy specimen (>1 cm) over a short-segment temporal artery biopsy specimen (<1 cm).

A longer segment of the temporal artery is preferred, since GCA is a focal and segmental disease, and the added morbidity of obtaining a larger segment is very low. A shorter segment obtained on biopsy can result in reduced diagnostic yield and a missed diagnosis. This recommendation is conditional due to a lack of high-quality evidence, but the Voting Panel emphasized obtaining longer biopsy specimens when possible (18,19).

Recommendation: For patients with suspected GCA, we conditionally recommend obtaining a temporal artery biopsy specimen within 2 weeks of starting oral glucocorticoids over waiting longer than 2 weeks for a biopsy.

Overall, biopsy specimens should be obtained as soon as possible to maximize the likelihood of detecting histopathologic changes. Studies suggest that histopathologic changes indicating GCA are more likely to be detected in a temporal artery biopsy if obtained within 2 weeks of starting glucocorticoids; however, histopathologic changes have been detected in biopsy specimens obtained much later than 2 weeks after the start of glucocorticoid treatment (20–28). A biopsy specimen obtained 2 weeks after starting glucocorticoids could be informative and may be considered at the discretion of the physician and patient.

Recommendation: For patients with suspected GCA, we conditionally recommend temporal artery biopsy over temporal artery ultrasound for establishing a diagnosis of GCA.

In general, rheumatologists and radiologists in the US are less experienced in using ultrasound to diagnose temporal artery involvement in GCA compared to their counterparts in Europe. Therefore, temporal artery biopsy remains the optimal approach to diagnosing GCA in the US, because ultrasound is operator-dependent and results are influenced by treatment (i.e., signs of inflammation quickly disappear with glucocorticoid treatment). In centers with appropriate training and expertise in using temporal artery ultrasound, ultrasound may be a useful and complementary tool for diagnosing GCA (29–33).

Table 2. Recommendations for diagnostic testing in GCA*

Recommendation	GCA PICO question informing recommendation and discussion	Level of evidence
Recommendation: For patients with suspected GCA, we conditionally recommend an initial unilateral temporal artery biopsy over bilateral biopsies.	1	Low
Recommendation: For patients with suspected GCA, we conditionally recommend a long-segment temporal artery biopsy specimen (>1 cm) over a short-segment temporal artery biopsy specimen (<1 cm).	2	Low
Recommendation: For patients with suspected GCA, we conditionally recommend obtaining a temporal artery biopsy specimen within 2 weeks of starting oral GCs over waiting longer than 2 weeks for a biopsy.	3	Low
Recommendation: For patients with suspected GCA, we conditionally recommend temporal artery biopsy over temporal artery ultrasound for establishing a diagnosis of GCA.	4	Low
Recommendation: For patients with suspected GCA, we conditionally recommend temporal artery biopsy over MRI of the cranial arteries for establishing a diagnosis of GCA.	5	Low
Recommendation: For patients with suspected GCA and a negative temporal artery biopsy result (or results), we conditionally recommend noninvasive vascular imaging of the large vessels with clinical assessment to aid in diagnosis over clinical assessment alone.	6, 7	Very low to low
Recommendation: For patients with newly diagnosed GCA, we conditionally recommend obtaining noninvasive vascular imaging to evaluate large vessel involvement.	9	Very low

* For the population, intervention, comparator, and outcome (PICO) questions used in the Grading of Recommendations Assessment, Development and Evaluation methodology, as developed for giant cell arteritis (GCA), please refer to Supplementary Appendix 2 (available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24632/abstract). GCs = glucocorticoids; MRI = magnetic resonance imaging.

Table 3. Recommendations/statements for treatment (medical management and surgical intervention) and clinical/laboratory monitoring in GCA*

Recommendation/statement	GCA PICO question informing recommendation and discussion	Level of evidence
Medical management		
Recommendation: For patients with newly diagnosed GCA without manifestations of cranial ischemia, we conditionally recommend initiating treatment with high-dose oral GCs over IV pulse GCs.	11	Very low to low
Recommendation: For patients with newly diagnosed GCA with threatened vision loss, we conditionally recommend initiating treatment with IV pulse GCs over high-dose oral GCs.	12	Very low
Recommendation: For patients with newly diagnosed GCA, we conditionally recommend dosing oral GCs daily over an alternate-day schedule.	18	Low
Recommendation: For patients with newly diagnosed GCA, we conditionally recommend initiating treatment with high-dose oral GCs over moderate-dose oral GCs.	14	Very low to low
Recommendation: For patients with newly diagnosed GCA, we conditionally recommend the use of oral GCs with tocilizumab over oral GCs alone.	15, 16, 17	Low to high
Recommendation: For patients with GCA with active extracranial large vessel involvement, we conditionally recommend treatment with oral GCs combined with a non-GC immunosuppressive agent over oral GCs alone.	21	Very low to low
Ungraded position statement: The optimal duration of therapy with GCs for GCA is not well established and should be guided by the patient's values and preferences.	20	Low to moderate
Recommendation: In patients with newly diagnosed GCA, we conditionally recommend *against* the use of an HMG-CoA reductase inhibitor ("statin") specifically for the treatment of GCA.	19	Very low
Recommendation: For patients with GCA who have critical or flow-limiting involvement of the vertebral or carotid arteries, we conditionally recommend adding aspirin.	13	Very low to moderate
Recommendation: For patients with GCA who experience disease relapse while receiving moderate-to-high–dose GCs, we conditionally recommend adding a non-GC immunosuppressive drug.	Relapse 2	†
Recommendation: For patients with GCA who experience disease relapse with symptoms of cranial ischemia, we conditionally recommend adding a non-GC immunosuppressive agent and increasing the dose of GCs over increasing the dose of GCs alone.	Relapse 1, 3	†
Recommendation: For patients with GCA who experience disease relapse with symptoms of cranial ischemia while receiving GCs, we conditionally recommend adding tocilizumab and increasing the dose of GCs over adding methotrexate and increasing the dose of GCs.	Relapse 4	†
Surgical intervention		
Ungraded position statement: For any patient requiring surgical vascular intervention for GCA, the type and timing of intervention should be a collaborative decision between the vascular surgeon and rheumatologist.	‡	‡
Recommendation: For patients with severe GCA and worsening signs of limb/organ ischemia who are receiving immunosuppressive therapy, we conditionally recommend escalating immunosuppressive therapy over surgical intervention with escalation of immunosuppressive therapy.	24	Very low to low
Recommendation: For patients with GCA undergoing vascular surgical intervention, we conditionally recommend the use of high-dose GCs during the periprocedural period, if the patient has active disease.	27	Very low
Clinical/laboratory monitoring		
Recommendation: For patients with GCA in apparent clinical remission, we strongly recommend long-term clinical monitoring over no clinical monitoring.	10	Very low to low
Recommendation: For patients with GCA who have an increase in levels of inflammation markers alone, we conditionally recommend clinical observation and monitoring without escalation of immunosuppressive therapy.	23	Very low

* For the population, intervention, comparator, and outcome (PICO) questions used in the Grading of Recommendations Assessment, Development and Evaluation methodology, as developed for giant cell arteritis (GCA), please refer to Supplementary Appendix 2 (available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24632/abstract). GCs = glucocorticoids; IV = intravenous; HMG-CoA = hydroxymethylglutaryl-coenzyme A.
† PICO question was developed after completion of literature review and evidence reports. Data from studies already included in evidence reports were reviewed, but no dedicated literature review was performed for these questions. Recommendation was formed from available evidence and expert opinion.
‡ Ungraded position statement was not based on a specific PICO question.

Recommendation: For patients with suspected GCA, we conditionally recommend temporal artery biopsy over magnetic resonance imaging (MRI) of the cranial arteries for establishing a diagnosis of GCA.

Protocols to image the cranial vessels using different modalities, including MRI, have been developed, which can be helpful to establish a diagnosis of GCA (30,31,34–37). However, lack of technical expertise with this modality in the US, as well as the lack of widespread validation of this approach, limits the applicability of MRI with contrast of the cranial vessels as a replacement for temporal artery biopsy at the current time.

Figure 1. Overview of treatment of giant cell arteritis.

Recommendation: For patients with suspected GCA and a negative temporal artery biopsy result (or results), we conditionally recommend noninvasive vascular imaging of the large vessels with clinical assessment to aid in diagnosis over clinical assessment alone.

Imaging the large vessels may provide additional evidence of disease (e.g., extracranial GCA) when the diagnosis is uncertain following negative temporal artery biopsy results (28,34,38–44). Potential diagnostic imaging modalities include MR or computed tomography (CT) angiography of the neck/chest/abdomen/pelvis, ultrasonography, and ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) (43,45).

Recommendation: For patients with newly diagnosed GCA, we conditionally recommend obtaining noninvasive vascular imaging to evaluate large vessel involvement.

Baseline noninvasive imaging with MR or CT angiography of the neck/chest/abdomen/pelvis in patients with newly diagnosed GCA can detect large vessel involvement and may be compared with subsequent routine monitoring if indicated (46). In a patient with large vessel involvement, routine noninvasive vascular imaging can identify early and long-term complications, such as aneurysms and stenoses, and assess stability of existing lesions. In patients without large vessel involvement, routine and repeated monitoring with vascular imaging may or may not be necessary.

Medical management

Recommendation: For patients with newly diagnosed GCA without manifestations of cranial ischemia, we conditionally recommend initiating treatment with high-dose oral glucocorticoids over intravenous (IV) pulse glucocorticoids.

Cranial ischemic manifestations include visual and neurologic involvement such as amaurosis fugax, vision loss, and stroke. Some studies have suggested that the use of IV pulse glucocorticoids in this patient group could decrease disease relapse and increase remission rates. However, routine use of IV pulse glucocorticoids can also be associated with increased risks, including infections, that may outweigh the benefits, especially in the elderly (47,48).

Recommendation: For patients with newly diagnosed GCA with threatened vision loss, we conditionally recommend initiating treatment with IV pulse glucocorticoids over high-dose oral glucocorticoids.

Studies investigating the effect of IV pulse glucocorticoids in patients with GCA and cranial ischemia have demonstrated conflicting results. However, this population is at high risk for vision loss as well as toxicity from glucocorticoid use. IV pulse glucocorticoids can be used in patients with the highest risk of vision loss, but this decision should be guided by the patient's clinical condition, values, and preferences (49,50).

Recommendation: For patients with newly diagnosed GCA, we conditionally recommend dosing oral glucocorticoids daily over an alternate-day schedule.

This recommendation is conditional solely due to the low level of evidence, which indicates higher remission rates in patients receiving daily dosing. The panel did not identify any situations in which alternate-day dosing of prednisone would be preferred (51).

Recommendation: For patients with newly diagnosed GCA, we conditionally recommend initiating treatment with high-dose oral glucocorticoids over moderate-dose oral glucocorticoids.

We recommend starting high-dose oral glucocorticoids to achieve rapid disease control followed by tapering the glucocorticoid dose (weeks to months) to avoid prolonged high-dose treatment and reduce toxicity. The dosing and duration of oral glucocorticoid therapy can be variable depending on a patient's manifestations and comorbidities and whether the use of a glucocorticoid-sparing agent was also initiated. Studies supporting the efficacy and lower toxicity of moderate-dose glucocorticoids are of low quality, which prevents the Voting Panel from recommending moderate-dose glucocorticoids as initial therapy. Moderate-dose glucocorticoids may be used in patients with significant risk of severe glucocorticoid toxicity and in patients with low risk of vision loss or other life- or organ-threatening complications (48–53).

Recommendation: For patients with newly diagnosed GCA, we conditionally recommend the use of oral glucocorticoids with tocilizumab over oral glucocorticoids alone.

A trial published in 2017 (8) demonstrated that tocilizumab has a significant glucocorticoid-sparing effect in GCA, and thus, tocilizumab should be considered for initial treatment. However, methotrexate with glucocorticoids, as well as glucocorticoids alone, can also be considered as initial treatment for newly diagnosed GCA. The decision to treat with tocilizumab and glucocorticoids, methotrexate and glucocorticoids, or glucocorticoid monotherapy for initial therapy should be made based on the physician's experience and the patient's clinical condition, values, and preferences. Lack of long-term follow-up data on tocilizumab and cost may limit its use (8,54). Abatacept with glucocorticoids can also be considered if these other agents are not effective (55).

Recommendation: For patients with GCA with active extracranial large vessel involvement, we conditionally recommend treatment with oral glucocorticoids combined with a nonglucocorticoid immunosuppressive agent over oral glucocorticoids alone.

Management of GCA in patients with new, persistent, or worsening extracranial symptoms (e.g., limb claudication) or signs (e.g., imaging findings) attributed to GCA can include the addition of nonglucocorticoid immunosuppressive agents. These agents include biologic agents (e.g., tocilizumab) as well as oral therapies (e.g., methotrexate) (56,57). However, the Voting Panel recognizes that there are few high-quality studies evaluating the efficacy of these agents for this patient group. While there is stronger clinical evidence supporting the use of tocilizumab compared to methotrexate for the treatment of GCA, methotrexate can be considered for patients unable to use tocilizumab due to factors such as recurrent infections, history of gastrointestinal perforations or diverticulitis, and cost.

Ungraded position statement: The optimal duration of therapy with glucocorticoids for GCA is not well established and should be guided by the patient's values and preferences.

Factors that may influence the duration of therapy include the patient's clinical manifestations, toxicity related to glucocorticoid use, number of flares, the physician's experience, and the patient's preferences (8). Overall, the Patient Panel emphasized minimizing the use of glucocorticoids as much as possible but recognized that longer-term use may be needed in some patients to avoid flares.

Recommendation: In patients with newly diagnosed GCA, we conditionally recommend *against* the use of a hydroxymethylglutaryl-coenzyme A reductase inhibitor ("statin") specifically for the treatment of GCA.

The use of statins is not known to provide a clinically significant immunosuppressive effect for GCA. Whether statins are warranted to decrease the patient's risk of cardiovascular events is a separate clinical question and depends on the patient's risk factors for cardiovascular disease (58–60).

Recommendation: For patients with GCA who have critical or flow-limiting involvement of the vertebral or carotid arteries, we conditionally recommend adding aspirin.

There are few data regarding this clinical question, but the antiplatelet activity of aspirin may be beneficial in preventing ischemic events in patients with vascular narrowing causing decreased cerebral blood flow (61–64). The efficacy of aspirin to prevent ischemic events in patients without vertebral or carotid narrowing remains unclear at this time.

Recommendation: For patients with GCA who experience disease relapse while receiving moderate-to-high–dose glucocorticoids, we conditionally recommend adding a nonglucocorticoid immunosuppressive drug.

Relapses of any type while receiving moderate-to-high–dose glucocorticoids indicate that it is unlikely that it will be possible for glucocorticoids to be tapered to a low dose. Therefore, glucocorticoid-sparing therapy should be considered.

Recommendation: For patients with GCA who experience disease relapse with symptoms of cranial ischemia, we conditionally recommend adding a nonglucocorticoid immunosuppressive agent and increasing the dose of glucocorticoids over increasing the dose of glucocorticoids alone.

Nonglucocorticoid immunosuppressive agents considered in this situation include tocilizumab and methotrexate (8,65,66). Relapses with symptoms of polymyalgia rheumatica may be controlled by increasing the dose of glucocorticoids alone.

Recommendation: For patients with GCA who experience disease relapse with cranial symptoms while receiving glucocorticoids, we conditionally recommend adding tocilizumab and increasing the dose of glucocorticoids over adding methotrexate and increasing the dose of glucocorticoids.

Tocilizumab is an effective glucocorticoid-sparing agent for GCA (8,54). While there are no comparative studies, the glucocorticoid-sparing effect seen with methotrexate is smaller than the effect seen with tocilizumab (8,55,65–67). While the glucocorticoid-sparing effect of tocilizumab is best quantified using the subcutaneous formulation (8), IV tocilizumab has also been shown to be glucocorticoid-sparing (54). Again, methotrexate can be considered for patients who are unable to tolerate or have limited access to tocilizumab.

Surgical intervention

Ungraded position statement: For any patient requiring surgical vascular intervention for GCA, the type and timing of intervention should be a collaborative decision between the vascular surgeon and rheumatologist.

Recommendation: For patients with severe GCA and worsening signs of limb/organ ischemia who are receiving immunosuppressive therapy, we conditionally recommend escalating immunosuppressive therapy over surgical intervention with escalation of immunosuppressive therapy.

Because patients can develop collateral blood vessels to improve distal blood flow, immunosuppressive therapy is recommended as initial therapy in patients with GCA and worsening limb/organ ischemia. However, clinical situations that would warrant consideration of immediate surgical intervention include aortic aneurysms at high risk for rupture and impending/progressive tissue or organ infarction or damage (68–70).

Recommendation: For patients with GCA undergoing vascular surgical intervention, we conditionally recommend the use of high-dose glucocorticoids during the periprocedural period, if the patient has active disease.

This recommendation pertains to patients with GCA who are undergoing a vascular surgical intervention due to a complication of GCA (e.g., aneurysm or stenosis). There are limited data regarding the use of high-dose glucocorticoids during the periprocedural period in GCA, and thus, support for this recommendation is based in part on their use in TAK. As in TAK, high doses of oral glucocorticoids in the perioperative setting are recommended if the disease is active or if the clinician is concerned that the patient may have active disease.

Clinical/laboratory monitoring

Recommendation: For patients with GCA in apparent clinical remission, we strongly recommend long-term clinical monitoring over no clinical monitoring.

The optimal frequency and length of monitoring are not well established and depend on factors including the duration of remission, site of involvement, risk of disease progression, whether the patient is receiving immunosuppressive therapy, and reliability of the patient to report new signs or symptoms (48,69). Clinical monitoring may include history taking, examinations, and laboratory and imaging studies. This is a strong recommendation given the minimal risks and potential catastrophic outcomes if monitoring is not performed.

Recommendation: For patients with GCA who have an increase in levels of inflammation markers alone, we conditionally recommend clinical observation and monitoring without escalation of immunosuppressive therapy.

Increases in levels of inflammation markers such as erythrocyte sedimentation rate and C-reactive protein can be nonspecific (69). Therefore, increasing immunosuppressive therapy is not warranted in the setting of increased levels of inflammation markers in the absence of other signs of disease activity. However, these increased levels may warrant more frequent clinical and/or radiographic assessments for active disease.

Recommendations and ungraded position statement for the management of TAK

Table 1 presents definitions of selected terms used in the recommendations, and Tables 4 and 5 present the recommendations with their supporting PICO questions and levels of evidence. We present 20 recommendations and 1 ungraded position statement for TAK. All recommendations except for 1 are conditional due to the availability of only very low– to low-quality evidence. Figure 2 presents key recommendations for the treatment of TAK.

Medical management

Recommendation: For patients with active, severe TAK who are not receiving immunosuppressive therapy, we conditionally recommend initiating treatment with high-dose oral glucocorticoids over IV pulse glucocorticoids followed by high-dose oral glucocorticoids.

There is no evidence that IV pulse glucocorticoids are more effective than high-dose oral glucocorticoids in this setting.

IV pulse glucocorticoids may be considered for patients with life- or organ-threatening disease. In children, alternate steroid dosing regimens (e.g., IV pulse glucocorticoids with low daily oral dosing) may be preferred to improve compliance and potentially reduce adverse consequences such as impacting growth (71).

Recommendation: For patients with newly active, severe TAK, we conditionally recommend initiating treatment with high-dose glucocorticoids over low-dose glucocorticoids.

A higher dose of glucocorticoids is recommended due to the potential for organ damage or life-threatening events. However, lower doses of glucocorticoids may be considered for patients with newly active, nonsevere disease (e.g., patients with constitutional symptoms and without limb ischemia) (72).

Recommendation: For patients with TAK who achieved remission while receiving glucocorticoids for ≥6–12 months, we conditionally recommend tapering off glucocorticoids over long-term treatment with low-dose glucocorticoids for remission maintenance.

The optimal duration of glucocorticoid use in TAK is unknown. Glucocorticoid exposure should be limited if possible in order to minimize toxicity. Glucocorticoids may be continued for a longer duration if disease is not adequately controlled or if the patient experiences frequent disease relapse.

Table 4. Recommendations/statement for treatment (medical management and surgical intervention) in TAK*

Recommendation/statement	TAK PICO question informing recommendation and discussion	Level of evidence
Medical management		
Recommendation: For patients with active, severe TAK who are not receiving immunosuppressive therapy, we conditionally recommend initiating treatment with high-dose oral GCs over IV pulse GCs followed by high-dose oral GCs.	6	Very low
Recommendation: For patients with newly active, severe TAK, we conditionally recommend initiating treatment with high-dose GCs over low-dose GCs.	5	Very low to low
Recommendation: For patients with TAK who achieved remission while receiving GCs for ≥6–12 months, we conditionally recommend tapering off GCs over long-term treatment with low-dose GCs for remission maintenance.	15	Very low
Recommendation: For patients with active TAK, we conditionally recommend the use of a non-GC immunosuppressive agent plus GCs over GCs alone.	7, 8, 9	Low
Recommendation: For patients with active TAK, we conditionally recommend the use of other non-GC immunosuppressive therapy over tocilizumab as initial therapy.	8, 10, 11, 12	Very low to low
Recommendation: For patients with TAK that is refractory to treatment with GCs alone, we conditionally recommend adding a tumor necrosis factor inhibitor over adding tocilizumab.	14	Very low
Recommendation: For patients with TAK and asymptomatic progression of a previously identified vascular lesion seen on imaging, without evidence of inflammation, we conditionally recommend continuing current therapy over escalating/changing immunosuppressive therapy.	16	Very low
Recommendation: For patients with active TAK and critical cranial or vertebrobasilar involvement, we conditionally recommend adding aspirin or another antiplatelet therapy.	13	Low
Surgical intervention		
Ungraded position statement: For any patient requiring surgical vascular intervention, the type and timing of intervention should be a collaborative decision between the vascular surgeon and rheumatologist.	†	†
Recommendation: In patients with known TAK and persistent limb claudication without evidence of ongoing active disease, we conditionally recommend *against* surgical intervention.	20	Very low to low
Recommendation: For patients with known TAK with worsening signs of limb/organ ischemia while receiving immunosuppressive therapy, we conditionally recommend escalating immunosuppressive therapy over surgical intervention with escalation of immunosuppressive therapy.	21, 24	Very low
Recommendation: For patients with TAK with renovascular hypertension and renal artery stenosis, we conditionally recommend medical management over surgical intervention.	26	Very low to low
Recommendation: For patients with TAK and stenosis of a cranial/cervical vessel without clinical symptoms, we conditionally recommend medical management over surgical intervention.	22	Very low to low
Recommendation: For patients with TAK with worsening signs of limb/organ ischemia, we conditionally recommend delaying surgical intervention until the disease is quiescent over performing surgical intervention while the patient has active disease.	23	Very low to low
Recommendation: For patients with TAK who are undergoing surgical intervention, we conditionally recommend the use of high-dose GCs in the periprocedure period if the patient has active disease.	25	Very low to low

* For the population, intervention, comparator, and outcome (PICO) questions used in the Grading of Recommendations Assessment, Development and Evaluation methodology, as developed for Takayasu arteritis (TAK), please refer to Supplementary Appendix 2 (available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24632/abstract). GCs = glucocorticoids; IV = intravenous.
† Ungraded position statement was not based on a specific PICO question.

Table 5. Recommendations for clinical/laboratory monitoring and vascular imaging in TAK*

Recommendation	TAK PICO question informing recommendation and discussion	Level of evidence
Clinical/laboratory monitoring		
Recommendation: For patients with TAK, we conditionally recommend adding inflammation markers to clinical monitoring as a disease activity assessment tool.	2	Very low to low
Recommendation: For patients with TAK in apparent clinical remission, we strongly recommend long-term clinical monitoring over no clinical monitoring.	4	Very low
Recommendation: For patients with TAK in apparent clinical remission but with an increase in levels of inflammation markers, we conditionally recommend clinical observation without escalation of immunosuppressive therapy.	19	Very low
Vascular imaging		
Recommendation: For patients with TAK, we conditionally recommend the use of noninvasive imaging over catheter-based dye angiography as a disease activity assessment tool.	1	Low
Recommendation: For patients with known TAK, we conditionally recommend regularly scheduled noninvasive imaging in addition to routine clinical assessment.	3	Very low to low
Recommendation: For patients with TAK in apparent clinical remission but with signs of inflammation in new vascular territories (e.g., new stenosis or vessel wall thickening) on vascular imaging, we conditionally recommend treatment with immunosuppressive therapy.	17, 18	Very low to low

* For the population, intervention, comparator, and outcome (PICO) questions used in the Grading of Recommendations Assessment, Development and Evaluation methodology, as developed for Takayasu arteritis (TAK), please refer to Supplementary Appendix 2 (available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24632/abstract).

Recommendation: For patients with active TAK, we conditionally recommend the use of a nonglucocorticoid immunosuppressive agent plus glucocorticoids over glucocorticoids alone.

Nonglucocorticoid immunosuppressive agents are recommended over monotherapy with glucocorticoids to minimize glucocorticoid-related toxicity. Methotrexate is often used as the initial nonglucocorticoid immunosuppressive agent, but other therapies such as tumor necrosis factor inhibitors and azathioprine can be considered as well (70–73). Methotrexate is often preferred for use in children since it is usually well tolerated. Glucocorticoid monotherapy can be considered for mild disease or if the diagnosis is uncertain.

Figure 2. Overview of treatment of Takayasu arteritis based on clinical and radiographic assessments.

Patient-specific factors such as alcohol use, plans for childbearing, medication compliance, and medical comorbidities may influence the choice of immunosuppressant (73,74).

Recommendation: For patients with active TAK, we conditionally recommend the use of other nonglucocorticoid immunosuppressive therapy over tocilizumab as initial therapy.

As discussed above, nonglucocorticoid immunosuppressive agents such as methorexate, tumor necrosis factor inhibitors, and azathioprine can be used as initial therapy in TAK. We recommend these agents over tocilizumab for initial therapy, because the efficacy of tocilizumab in TAK is not established at this time. While tocilizumab has been shown to be efficacious for GCA, the primary efficacy end point was not achieved in the only randomized trial of tocilizumab in TAK conducted thus far (74,75). Tocilizumab may be considered for patients with inadequate response to other immunosuppressive therapies. Abatacept is not recommended, since it has been shown in a small randomized controlled trial to not be efficacious in TAK (74,76).

Recommendation: For patients with TAK that is refractory to treatment with glucocorticoids alone, we conditionally recommend adding a tumor necrosis factor inhibitor over adding tocilizumab.

We recognize that among biologic therapies, some practitioners favor TNF inhibition, while others favor interleukin-6 inhibition (tocilizumab) in this situation. Overall, the Voting Panel favored tumor necrosis factor inhibitors over tocilizumab, since there is more clinical experience with and data on tumor necrosis factor inhibitors in TAK compared to tocilizumab. In observational studies, tumor necrosis factor inhibitors have been shown to induce remission and decrease relapses (77–79). Clinical experience with tocilizumab in TAK has been demonstrated in a randomized controlled trial and small case series. In the randomized trial, a trend toward a longer time to relapse was seen in the tocilizumab arm, but the difference was not statistically significant. However, that study was felt to be underpowered (36 participants). Of note, tocilizumab use also affects acute-phase reactants, which may impact ability to gauge disease activity. Therefore, while the panel favors tumor necrosis factor inhibitor use, we recognize that tocilizumab may also be considered, especially when tumor necrosis factor inhibitors are contraindicated (75).

Recommendation: For patients with TAK and asymptomatic progression of a previously identified vascular lesion seen on imaging, without evidence of inflammation, we conditionally recommend continuing current therapy over escalating/changing immunosuppressive therapy.

Vascular lesions can progress due to a number of factors that may not be related to active disease, such as "healing fibrosis" in response to effective treatment. Intervention is not always needed, since collateral circulation frequently develops over time. However, the location and the extent of the lesion of the affected vessel should be considered. Escalating immunosuppressive therapy may be warranted if significant progression has developed rapidly (e.g., weeks to months) after a period of stable disease (80,81).

Recommendation: For patients with active TAK and critical cranial or vertebrobasilar involvement, we conditionally recommend adding aspirin or another antiplatelet therapy.

Small observational studies suggest a decreased risk of ischemic events with antiplatelet therapy but an increased risk of bleeding (82). Therefore, antiplatelet therapy is usually used for patients at higher risk of ischemic events (e.g., patients with flow-limiting vertebrobasilar disease or stents). Antiplatelet therapy should be used with caution after surgical procedures or if there is an increased risk of bleeding (81).

Clinical/laboratory monitoring

Recommendation: For patients with TAK, we conditionally recommend adding inflammation markers to clinical monitoring as a disease activity assessment tool.

While inflammation markers are an imperfect indicator of disease activity, they may be helpful for clinical monitoring (80,83).

Recommendation: For patients with TAK in apparent clinical remission, we strongly recommend long-term clinical monitoring over no clinical monitoring.

The frequency of monitoring depends on factors including the duration of remission, sites of involvement, risk of disease progression, the patient's immunosuppressive regimen, and the ability and likelihood of the patient reliably reporting new signs or symptoms of TAK. This is a strong recommendation given the minimal risks and potential catastrophic outcomes without monitoring (80,83).

Recommendation: For patients with TAK in apparent clinical remission but with an increase in levels of inflammation markers, we conditionally recommend clinical observation without escalation of immunosuppressive therapy.

As discussed above in the GCA recommendations, increases in levels of inflammation markers can be nonspecific, and intensifying immunosuppressive therapy in the setting of increased inflammation markers alone may not be warranted. More frequent clinical and/or radiographic assessments for active disease can be considered (77,80,83).

Vascular imaging

Recommendation: For patients with TAK, we conditionally recommend the use of noninvasive imaging over catheter-based dye angiography as a disease activity assessment tool.

Noninvasive imaging such as CT angiography, MR angiography, or FDG-PET are recommended because these imaging modalities provide information regarding vascular wall inflammation, while catheter-based angiography primarily provides information regarding the vascular lumen. Catheter-based angiography can be used to accurately determine central blood pressures, as part of surgical planning, or if noninvasive modalities do not provide adequate information. Identifying active disease based on noninvasive imaging at this time can be challenging, since the hallmarks of active disease have not been definitively established (43,45,84).

Recommendation: For patients with known TAK, we conditionally recommend regularly scheduled noninvasive imaging in addition to routine clinical assessment.

Routine imaging is recommended since vascular changes in TAK can occur when the disease is considered clinically quiescent. The optimal interval between imaging studies is not well established, and ranges vary (e.g., every 3–6 months or longer). The interval may be shorter early in the disease course and longer with established, quiescent disease. Since sedation may be required for imaging studies in children and can be associated with potential risks and complications, routine imaging of inactive disease in children is at the discretion of the treating clinician, while considering risks and benefits (85,86).

Recommendation: For patients with TAK in apparent clinical remission but with signs of inflammation in new vascular territories (e.g., new stenosis or vessel wall thickening) on vascular imaging, we conditionally recommend treatment with immunosuppressive therapy.

A new arterial stenosis is concerning as it can indicate recent active disease, and thus usually warrants immunosuppressive therapy. Other findings suggestive of active disease on MR angiography or CT angiography include vascular edema, contrast enhancement, and increased wall thickness, and may result in luminal damage over time. Findings of active disease by FDG-PET are defined by supraphysiologic FDG uptake in the arterial wall. However, abnormal findings in the vascular wall identified by imaging are not necessarily specific to vascular inflammation. The implication of finding vessel wall edema or enhancement on imaging remains an area of investigation, and the clinical importance of such findings on CT angiography, MR angiography, or FDG-PET is not certain (43,45,80,83–86). Therefore, all therapeutic decision-making in this context should occur after reviewing the imaging findings with a radiologist to help determine whether the observed imaging changes represent active disease.

Surgical intervention

Ungraded position statement: For any patient requiring surgical vascular intervention, the type and timing of intervention should be a collaborative decision between the vascular surgeon and rheumatologist.

Recommendation: In patients with known TAK and persistent limb claudication without evidence of ongoing active disease, we conditionally recommend *against* surgical intervention.

Patients with TAK can develop collateral circulation that bypasses the stenosis causing limb claudication, and thus, surgical intervention may not be needed (87). However, surgical intervention can be considered for patients whose activities are significantly impacted by limb claudication.

Recommendation: For patients with known TAK with worsening signs of limb/organ ischemia while receiving immunosuppressive therapy, we conditionally recommend escalating immunosuppressive therapy over surgical intervention with escalation of immunosuppressive therapy.

Immunosuppressive therapy is recommended to control vascular inflammation in order to improve or prevent worsening blood flow. However, clinical situations that could warrant immediate surgical intervention include coronary artery involvement and impending/progressive tissue or organ infarction (88–90).

Recommendation: For patients with TAK with renovascular hypertension and renal artery stenosis, we conditionally recommend medical management over surgical intervention.

Medical management includes antihypertensive drugs and immunosuppressive therapy if TAK is active. Surgical intervention (including catheter-based interventions) may be warranted for hypertension that is refractory to medical management in spite of optimized immunosuppressive therapy or in the setting of worsening renal function (12,91–94).

Recommendation: For patients with TAK and stenosis of a cranial/cervical vessel without clinical symptoms, we conditionally recommend medical management over surgical intervention.

Medical therapy is recommended if only a single vessel is involved, due to the substantial risks of surgery. Surgical interventions can be considered if multiple vessels are involved. This recommendation is based on indirect evidence obtained from neurologic experience and studies, because there is no direct evidence for TAK (90,95–98).

Recommendation: For patients with TAK with worsening signs of limb/organ ischemia, we conditionally recommend delaying surgical intervention until the disease is quiescent over performing surgical intervention while the patient has active disease.

Observational studies have suggested improved outcomes if surgical intervention is performed when disease is not active. However, surgical intervention during active disease may be necessary if the patient has life- or organ-threatening manifestations such as stroke, loss of viability of a limb, or myocardial ischemia (99–101). We recognize that determining the level of disease activity in TAK can be challenging.

Recommendation: For patients with TAK who are undergoing surgical intervention, we conditionally recommend the use of high-dose glucocorticoids in the periprocedure period if the patient has active disease.

This recommendation pertains to patients with TAK who are undergoing a vascular surgical intervention due to a complication of TAK. High doses of oral glucocorticoids in the perioperative setting are recommended if the disease is active or if the clinician is concerned that the patient may have active disease (90,96,102).

DISCUSSION

This guideline presents the ACR/Vasculitis Foundation recommendations for the use of diagnostic testing, treatment, clinical and laboratory monitoring, and surgical intervention for patients with GCA or TAK. Overarching themes of the recommendations include the preference, in the US, for temporal artery biopsy over cranial imaging studies for the diagnosis of GCA, the use of large vessel imaging for GCA and TAK for diagnosis and disease monitoring, and limiting glucocorticoid exposure in order to minimize toxicity. Almost all recommendations are conditional due to low-quality evidence, reflecting the paucity of randomized clinical trials in these diseases.

Our recommendations regarding the use of temporal artery imaging differ from those presented by the European Alliance of Associations for Rheumatology (EULAR). In its recommendations regarding the use of imaging in large vessel vasculitis, EULAR indicates that the diagnosis of GCA may be made with a positive imaging test (e.g., temporal artery ultrasound or MRI of the cranial vessels), without additional testing such as temporal artery biopsy (103). However, the imaging recommendations presented by EULAR assume adequate expertise with these modalities. In the US, there is limited experience with temporal artery ultrasound and MRI of the cranial vessels as a diagnostic replacement for temporal artery biopsy, and thus, we continue to recommend temporal artery biopsy as the diagnostic test of choice at this time. However, we hope and anticipate that as experience with imaging of the temporal arteries to detect GCA (e.g., temporal artery ultrasound, MRI, and/or FDG-PET) increases in the US, patients will be able to benefit from these diagnostic tests. Also, in contrast to EULAR, we favor initial treatment of GCA with glucocorticoids and a glucocorticoid-sparing agent, given the well-recognized toxicity of glucocorticoids (104,105).

When reviewing the data abstracted for the PICO questions, it was clear that many critical clinical questions remain unanswered for GCA and TAK, and the lack of sufficient clinical evidence for these questions is reflected in the ungraded position statements presented in this guideline. For example, the optimal duration of therapy for any treatment and how best to monitor disease status is unknown. Few glucocorticoid-sparing agents have been identified through high-quality data. Accurate and validated indicators of disease activity have not been established or widely used for GCA or TAK. Interpretation of imaging studies in GCA and TAK can be challenging, and the clinical significance of persistent vascular wall inflammation during clinically quiescent disease is unclear.

Given these critical gaps in knowledge, we encourage additional research into the management of GCA and TAK. Studies that may greatly benefit patient care include the following: 1) translational studies contributing to the understanding of disease pathogenesis to facilitate development of more targeted therapies; 2) randomized clinical trials identifying new therapeutic options for the management of GCA and TAK; 3) randomized clinical trials comparing the effectiveness of currently used immunosuppressive therapies; and 4) longitudinal studies with biospecimen collection and routine vascular imaging to identify biomarkers of disease activity, indicators of disease prognosis, and the clinical sequelae of abnormalities identified on vascular imaging. We are hopeful that additional investigations into GCA and TAK will enable a more tailored approach to disease management in order to improve outcomes and minimize treatment toxicities.

ACKNOWLEDGMENTS

We thank Anne M. Ferris, MBBS, Ora Gewurz-Singer, MD, Rula Hajj-Ali, MD, Eric Matteson, MD, MPH, Robert F. Spiera, MD, Linda Wagner-Weiner, MD, MS, and Kenneth J. Warrington, MD, for serving on the Expert Panel. We thank Antoine G. Sreih, MD and Gary S. Hoffman, MD, MS, for their contributions during the early phases of this project as members of the Core Team. Dr. Hoffman's participation ended July 2018 due to personal reasons. Dr. Sreih's involvement ended in December 2018 when he became primarily employed by industry, which precluded his continued participation in this project. We thank Joyce Kullman (Vasculitis Foundation) for her assistance with recruitment for the Patient Panel. We thank the patients who (along with authors Kathy A. Full and Omar I. Vitobaldi) participated in the Patient Panel meeting: Jane Ascroft, Scott A. Brunton, Dedra DeMarco, Thomas Fitzpatrick, Jenn Gordon, Maria S. Mckay, Sandra Nye, Stephanie Sakson, and Ben Wilson. We thank Robin Arnold, Catherine E. Najem, MD, MSCE, and Amit Aakash Shah, MD, MPH, for their assistance with the literature review. We thank the ACR staff, including Ms Regina Parker, for assistance in organizing the face-to-face meeting and coordinating the administrative aspects of the project, and Ms Robin Lane for assistance in manuscript preparation. We thank Ms Janet Waters for help in developing the literature search strategy and performing the initial literature search, and Ms Janet Joyce for performing the update searches.

AUTHOR CONTRIBUTIONS

All authors were involved in drafting the article or revising it critically for important intellectual content, and all authors approved the final version to be published. Drs. Maz, Chung, and Abril had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Study conception and design. Maz, Chung, Abril, Langford, Gorelik, Guyatt, Archer, Full, Grayson, Merkel, Seo, Stone, Sule, Sundel, Vitobaldi, Turner, Mustafa.

Acquisition of data. Maz, Chung, Langford, Abril, Gorelik, Full, Imundo, Kim, Merkel, Stone, Vitobaldi, Byram, Dua, Husainat, James, Kalot, Lin, Springer, Turgunbaev, Villa-Forte, Turner, Mustafa.

Analysis and interpretation of data. Maz, Chung, Langford, Abril, Gorelik, Archer, Conn, Full, Grayson, Ibarra, Imundo, Kim, Merkel, Rhee, Seo, Stone, Vitobaldi, Warner, Byram, Dua, Husainat, Kalot, Lin, Springer, Turgunbaev, Mustafa.

2022 American College of Rheumatology/EULAR Classification Criteria for Giant Cell Arteritis

Cristina Ponte,[1] Peter C. Grayson,[2] Joanna C. Robson,[3] Ravi Suppiah,[4] Katherine Bates Gribbons,[2] Andrew Judge,[5] Anthea Craven,[6] Sara Khalid,[6] Andrew Hutchings,[7] Richard A. Watts,[8] Peter A. Merkel,[9] and Raashid A. Luqmani,[6], for the DCVAS Study Group

This criteria set has been approved by the American College of Rheumatology (ACR) Board of Directors and the EULAR Executive Committee. This signifies that the criteria set has been quantitatively validated using patient data, and it has undergone validation based on an independent data set. All ACR/EULAR-approved criteria sets are expected to undergo intermittent updates.

The ACR is an independent, professional, medical and scientific society that does not guarantee, warrant, or endorse any commercial product or service.

Objective. To develop and validate updated classification criteria for giant cell arteritis (GCA).

Methods. Patients with vasculitis or comparator diseases were recruited into an international cohort. The study proceeded in 6 phases: 1) identification of candidate items, 2) prospective collection of candidate items present at the time of diagnosis, 3) expert panel review of cases, 4) data-driven reduction of candidate items, 5) derivation of a points-based risk classification score in a development data set, and 6) validation in an independent data set.

Results. The development data set consisted of 518 cases of GCA and 536 comparators. The validation data set consisted of 238 cases of GCA and 213 comparators. Age ≥50 years at diagnosis was an absolute requirement for classification. The final criteria items and weights were as follows: positive temporal artery biopsy or temporal artery halo sign on ultrasound (+5); erythrocyte sedimentation rate ≥50 mm/hour or C-reactive protein ≥10 mg/liter (+3); sudden visual loss (+3); morning stiffness in shoulders or neck, jaw or tongue claudication, new temporal headache, scalp tenderness, temporal artery abnormality on vascular examination, bilateral axillary involvement on imaging, and fluorodeoxyglucose–positron emission tomography activity throughout the aorta (+2 each). A patient could be classified as having GCA with a cumulative score of ≥6 points. When these criteria were tested in the validation data set, the model area under the curve was 0.91 (95% confidence interval [95% CI] 0.88–0.94) with a sensitivity of 87.0% (95% CI 82.0–91.0%) and specificity of 94.8% (95% CI 91.0–97.4%).

Conclusion. The 2022 American College of Rheumatology/EULAR GCA classification criteria are now validated for use in clinical research.

This article is published simultaneously in *Annals of the Rheumatic Diseases*.

The Diagnostic and Classification Criteria in Vasculitis (DCVAS) study, which included the development of this classification criteria, was funded by grants from the American College of Rheumatology (ACR), EULAR, the Vasculitis Foundation, and the University of Pennsylvania Vasculitis Center. This study was also supported by the Intramural Research Program of the National Institute of Arthritis and Musculoskeletal and Skin Diseases, NIH.

INTRODUCTION

Giant cell arteritis (GCA), formerly known as temporal arteritis, is the most common form of systemic vasculitis in patients aged ≥50 years (1). GCA is defined by granulomatous arteritis that affects large- and medium-sized blood vessels with a predisposition to affect the cranial arteries (2). Common presenting features of the disease include headache, constitutional symptoms, jaw claudication, scalp tenderness, visual disturbances, and elevated inflammatory markers (3).

In 1990, the American College of Rheumatology (ACR) endorsed classification criteria for GCA (4). These criteria were established before the widespread use of noninvasive and advanced vascular imaging modalities, which have become increasingly incorporated in the clinical assessment of GCA. Vascular ultrasound can be used to diagnose GCA, and depending on the clinical setting, a noncompressible "halo" sign of a temporal ± axillary artery may replace the need for temporal artery biopsy (TAB) (5–8). Moreover, vascular imaging has demonstrated that arterial involvement in GCA is not exclusively confined to the cranial arteries (9,10) and can commonly affect the aorta and primary branches in a pattern similar to Takayasu arteritis (TAK) (11,12).

The limitations of the ACR 1990 criteria for GCA have become more apparent in the conduct of recent clinical trials and other research studies, in which investigators typically modify the 1990 ACR criteria to reflect modern practice (6,13,14). Notably, the 1990 ACR criteria focus mostly on cranial features of GCA and do not perform well in classifying patients with disease predominantly affecting the larger arteries. The 1990 ACR criteria were derived using comparator populations which included many patients with small-vessel vasculitis, a form of vasculitis that is not typically difficult to differentiate from GCA. In addition, the 1990 ACR criteria for GCA followed the "number of criteria" rule, which considered each criterion to have equal weight as a classifier for the disease. Since then, methodologic advances in classification criteria have allowed movement toward weighted criteria with threshold scores that improve performance characteristics (15,16).

This article outlines the development and validation of the revised ACR/EULAR–endorsed classification criteria for GCA.

METHODS

An international Steering Committee comprising clinician investigators with expertise in vasculitis, statisticians, and data managers was assembled to oversee the overall development of classification criteria for primary vasculitis (17). A detailed and complete description of the methods involved in the development and validation of the classification criteria for GCA is located in the Supplementary Appendix 1 (http://onlinelibrary.wiley.com/doi/10.1002/art.42325). Briefly, the Steering Committee implemented a 6-stage plan using data-driven and consensus methodology to develop the following criteria.

Stage 1: generation of candidate classification items for the systemic vasculitides. Candidate classification items were generated by expert opinion and reviewed by a group of vasculitis experts across a range of specialties using nominal group technique.

Stage 2: Diagnostic and Classification Criteria for Vasculitis (DCVAS) prospective observational study. A prospective, international, multisite observational study was conducted (see Appendix A for study investigators and sites). Ethical approval was obtained from local ethics committees. Consecutive patients representing the full spectrum of vasculitides were recruited from academic and community practices. Patients were included if they were 18 years or older and had a diagnosis of vasculitis or a condition that mimics vasculitis (e.g., infection, malignancy, atherosclerosis). Patients with GCA could only be enrolled within 2 years of diagnosis. Only data present at diagnosis were used to develop the classification criteria.

Stage 3: expert review to derive a gold standard–defined set of cases of large-vessel vasculitis (LVV). Experts in vasculitis from a wide range of geographic locations and specialties (see Appendix A) reviewed all submitted cases of vasculitis and a random selection of vasculitis mimics. Each reviewer was asked to review ~50 submitted cases to confirm the diagnosis and to specify the degree of certainty of their diagnosis as follows: very certain, moderately certain, uncertain, or very uncertain. Only cases agreed upon with at least moderate certainty by 2 reviewers were retained for further analysis.

Stage 4: refinement of candidate items specifically for LVV. The Steering Committee conducted a data-driven process to reduce the number of candidate items of relevance to cases and comparators for LVV. Density plots were assessed to study age distribution at diagnosis and symptom onset for GCA

and TAK. Absolute age requirements versus incorporation of age as a candidate criteria item was considered. Items related to the vascular physical examination, vascular imaging, arterial biopsy, and laboratory values were combined or eliminated based on consensus review. Items were selected for exclusion if they had a prevalence of <5% within the data set, and/or they were not clinically relevant for classification criteria (e.g., related to infection, malignancy, or demography). Low-frequency items of clinical importance could be combined, when appropriate. Patterns of vascular imaging findings detected by vascular ultrasound, angiography, or positron emission tomography (PET) were defined by K-means clustering (18).

Stage 5: derivation of the final classification criteria for GCA. The DCVAS data set was split into development (70%) and validation (30%) sets. Comparisons were performed between cases of GCA and a randomly selected comparator group in the following proportions: TAK, 33.5%; other vasculitides that mimic GCA and TAK (isolated aortitis, primary central nervous system vasculitis, polyarteritis nodosa, Behçet's disease, and other LVV), 33.4%; and other diagnoses that mimic LVV (e.g., atherosclerosis, unspecific headache), 33.1%. Least absolute shrinkage and selection operator (lasso) logistic regression was used to identify predictors from the data set and create a parsimonious model including only the most important predictors (19). The final items in the model were formulated into a clinical risk-scoring tool, with each factor assigned a weight based on its respective regression coefficient. A threshold that best balanced sensitivity and specificity was identified for classification.

Stage 6: validation of the final classification criteria for GCA. Performance of the new criteria was validated in an independent set of cases and comparators. Performance of the final classification criteria was examined in specific subsets of patients with GCA using data from the combined development and validation sets to maximize sample sizes for the subgroups. Patients were studied according to different disease subtypes (biopsy-proven GCA and large-vessel GCA) and regions of the world (North America, Europe) where clinical strategies to assess GCA are known to differ (20). Biopsy-proven GCA was defined as definite vasculitis on TAB reported by the submitting physician, and large-vessel GCA was defined as vasculitic involvement of the aorta or its branch arteries on either angiography (computed tomography, magnetic resonance imaging, or catheter-based angiography), ultrasound, or PET, without vasculitis on TAB. Comparison was made between the measurement properties of the new classification criteria for GCA and the 1990 ACR classification criteria in the validation data set. Performance characteristics of the criteria were also tested in patients with TAK and compared to those with GCA diagnosed between the ages of 50 and 60 years.

RESULTS

Generation of candidate classification items for the systemic vasculitides. The Steering Committee identified >1,000 candidate items for the DCVAS Case Report Form (see Supplementary Appendix 2, http://onlinelibrary.wiley.com/doi/10.1002/art.42325).

DCVAS prospective observational study. Between January 2011 and December 2017, the DCVAS study recruited 6,991 participants from 136 sites in 32 countries. Information on the DCVAS sites, investigators, and study participants is listed in Supplementary Appendices 3, 4, and 5 (http://onlinelibrary.wiley.com/doi/10.1002/art.42325).

Expert review methodology to derive a gold standard–defined final set of cases of LVV. The LVV expert panel review process included 56 experts who reviewed vignettes derived from the Case Report Forms for 2,131 cases submitted with a diagnosis of LVV (1,608 [75.5% of Case Report Forms]), another type of vasculitis (118 [5.5% of Case Report Forms]), or a mimic of vasculitis (405 [19.0% of Case Report Forms]). Characteristics and the list of expert reviewers are shown in Supplementary Appendices 6 and 7 (http://onlinelibrary.wiley.com/doi/10.1002/art.42325). A sample vignette and the LVV expert panel review flow chart are shown in Supplementary Appendices 8 and 9 (http://onlinelibrary.wiley.com/doi/10.1002/art.42325). A total of 1,695 cases (80%) passed the main LVV process. An additional 373 cases of LVV and comparators, confirmed during a previous review process to derive the classification criteria for antineutrophil cytoplasmic antibody–associated vasculitis, were also included. In total, after both review processes, 2,068 cases were available for the stages 4 and 5 analyses.

The submitting physician diagnosis of GCA was confirmed in 913 of 1,137 cases (80.3%) after both expert panel reviews. The reasons for exclusion were diagnosis of GCA categorized as "uncertain" or "very uncertain" during panel review (n = 187) or change in diagnosis during panel review to another type of vasculitis (isolated aortitis, TAK, other vasculitides) (n = 11) or to a comparator disease (n = 26). An additional 29 patients who were not initially diagnosed as having GCA by the submitting physician were diagnosed as having GCA after panel review and DCVAS Steering Committee member adjudication. In total, 942 cases of confirmed GCA were available for analysis. To balance the number of cases of GCA with the number of available comparators, 756 cases of GCA were randomly selected for subsequent analysis.

Refinement of candidate items specifically for GCA. Only 7 of 942 patients with GCA (<1%) were diagnosed at age <50 years (see Supplementary Appendix 10 for the distribution of "age at diagnosis" in patients with LVV, and the similar

23265205, 0, Downloaded from https://onlinelibrary.wiley.com/doi/10.1002/art.42325, Wiley Online Library on [28/11/2022]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

distribution of "age at symptom onset," http://onlinelibrary.wiley.com/doi/10.1002/art.42325). Therefore, an age of ≥50 years at diagnosis was considered an absolute requirement to classify GCA. Cluster analyses of vascular imaging data identified bilateral axillary involvement and diffuse fluorodeoxyglucose uptake throughout the aorta on PET as specific imaging patterns for GCA (see Supplementary Appendices 11 and 12, http://onlinelibrary.wiley.com/doi/10.1002/art.42325). These imaging patterns were tested as potential classifiers.

Following a data-driven and expert consensus process, 72 items of the DCVAS Case Report Form were retained for regression analysis, including 32 demographic and clinical items, 14 laboratory items (including values of C-reactive protein [CRP] level and erythrocyte sedimentation rate [ESR], each divided into 5 categories), 14 imaging items (13 composite), 11 vascular examination items (5 composite, and upper extremity blood pressure divided into 6 categories), and 1 biopsy item (Supplementary Appendix 13, http://onlinelibrary.wiley.com/doi/10.1002/art.42325).

Derivation of the final classification criteria for GCA. A total of 1,505 patients were selected for analysis (756 GCA and 749 comparators), of which 1,054 (70%) were in the development data set (518 GCA and 536 comparators) and 451 (30%) in the validation data set (238 GCA and 213 comparators). Table 1 describes the demographic and clinical features of the patients with GCA and the comparators. The patients with GCA were recruited from Europe (n = 796), North America (n = 112), Oceania (n = 18), and Asia (n = 16). Clinical diagnoses assigned to patients in the comparator group are detailed in Supplementary Appendix 14 (http://onlinelibrary.wiley.com/doi/10.1002/art.42325).

Lasso regression of the previously selected 72 items yielded 27 independent predictor variables for GCA (Supplementary Appendix 15A, http://onlinelibrary.wiley.com/doi/10.1002/art.42325). Each predictor variable was then reviewed for inclusion by the DCVAS Steering Committee, based on their odds ratios and specificity to GCA, to ensure face validity. The variables "definitive vasculitis on TAB" and "halo sign on temporal artery ultrasound" were found to dominate the model as quite strong predictors of GCA (see Supplementary Appendix 16A for cluster plots showing almost a perfect overlap between the diagnosis of GCA and positive TAB or halo sign on temporal artery ultrasound, http://onlinelibrary.wiley.com/doi/10.1002/art.42325). Therefore, for the remaining variables to have discriminatory value, both of these items were removed from the model, combined into one composite item "vasculitis on TAB or halo sign on temporal artery ultrasound" and given a risk score of one point below the final threshold set to classify GCA to maintain face validity. The variables "jaw claudication" and "tongue claudication" were combined into 1 item, as were the variables "maximum ESR (>50 mm/hour)" and "maximum CRP (>10 mg/liter)." Although the variable "new persistent headache, occipital or cervical" showed important statistical significance, it decreased the overall specificity of the model when testing their final performance characteristics (patients versus comparators) and was, therefore, also removed. Weighting of the individual criterion

Table 1. Demographic and disease features of the patients with giant cell arteritis and the comparators*

	GCA (n = 756)	Comparators (n = 749)†	*P*
Age, mean ± SD years	72.2 ± 8.5	44.6 ± 18.0	<0.001
Female sex	511 (67.6)	447 (59.7)	0.001
Clinical features			
Morning stiffness, neck/torso	88 (11.6)	15 (2.0)	<0.001
Morning stiffness, shoulders/arms	174 (23.0)	23 (3.1)	<0.001
Sudden visual loss	102 (13.5)	29 (3.9)	<0.001
Jaw claudication	356 (47.1)	19 (2.5)	<0.001
Tongue claudication	21 (2.8)	1 (0.1)	<0.001
New persistent temporal headache	475 (62.8)	90 (12.0)	<0.001
Scalp tenderness	260 (34.4)	25 (3.3)	<0.001
Temporal artery abnormality on vascular examination‡	354 (46.8)	35 (4.7)	<0.001
Investigations			
Maximum ESR ≥50 mm/hour	558 (73.8)	291 (38.9)	<0.001
Maximum CRP ≥10 mg/liter	683 (90.3)	445 (59.4)	<0.001
Definitive vasculitis on temporal artery biopsy	335 (44.3)	1 (0.1)	<0.001
Halo sign on temporal artery ultrasound	211 (27.9)	1 (0.1)	<0.001
Bilateral axillary involvement on imaging§	57 (7.5)	12 (1.6)	<0.001
FDG-PET activity throughout aorta¶	52 (6.9)	9 (1.2)	<0.001

* Except where indicated otherwise, values are the number (%). ESR = erythrocyte sedimentation rate; CRP = C-reactive protein; FDG-PET = ^{18}F-fluorodeoxyglucose–positron emission tomography.
† Diagnoses of comparators for the classification criteria for giant cell arteritis (GCA) included Takayasu arteritis (n = 251), Behçet's disease (n = 133), polyarteritis nodosa (n = 74), isolated aortitis (n = 16), primary central nervous system vasculitis (n = 16), large-vessel vasculitis (LVV) that could not be subtyped (n = 9), other diseases that mimic LVV (n = 250).
‡ Absent or diminished pulse, tenderness, or hard 'cord like' appearance.
§ Defined as damage (i.e., stenosis, occlusion, or aneurysm) on angiography (computed tomography, magnetic resonance, or catheter-based) or ultrasound, halo sign on ultrasound, or abnormal FDG uptake on PET.
¶ Descending thoracic and abdominal aorta.

23265205, 0, Downloaded from https://onlinelibrary.wiley.com/doi/10.1002/art.42325, Wiley Online Library on [28/11/2022]. included in the model was based on logistic regression fitted to the remaining 9 selected predictors (Supplementary Appendix 17A, http://onlinelibrary.wiley.com/doi/10.1002/art.42325).

Validation of the final classification criteria for GCA. Using a cutoff of ≥6 in total risk score in the validation data set (see Supplementary Appendix 18A at https://onlinelibrary.wiley.com/doi/10.1002/art.42325 for different cutoff points), the sensitivity was 87.0% (95% confidence interval [95% CI] 82.0–91.0%) and specificity was 94.8% (95% CI 91.0–97.4%). The area under the curve for the model was 0.91 (95% CI 0.88–0.94) (Supplementary Appendix 19A, http://onlinelibrary.wiley.com/doi/10.1002/art.42325). The final 2022 ACR/EULAR classification criteria for GCA are presented in Figure 1 (for the slide presentation versions, see Supplementary Figure 1, http://onlinelibrary.wiley.com/doi/10.1002/art.42325).

2022 AMERICAN COLLEGE OF RHEUMATOLOGY / EULAR

CLASSIFICATION CRITERIA FOR **GIANT CELL ARTERITIS**

CONSIDERATIONS WHEN APPLYING THESE CRITERIA

- **These classification criteria should be applied to classify the patient as having giant cell arteritis when a diagnosis of medium-vessel or large-vessel vasculitis has been made**
- **Alternate diagnoses mimicking vasculitis should be excluded prior to applying the criteria**

ABSOLUTE REQUIREMENT

Age ≥ 50 years at time of diagnosis	

ADDITIONAL CLINICAL CRITERIA

Morning stiffness in shoulders/neck	+2
Sudden visual loss	+3
Jaw or tongue claudication	+2
New temporal headache	+2
Scalp tenderness	+2
Abnormal examination of the temporal artery[1]	+2

LABORATORY, IMAGING, AND BIOPSY CRITERIA

Maximum ESR ≥ 50 mm/hour or maximum CRP ≥ 10 mg/liter[2]	+3
Positive temporal artery biopsy or halo sign on temporal artery ultrasound[3]	+5
Bilateral axillary involvement[4]	+2
FDG-PET activity throughout aorta[5]	+2

Sum the scores for 10 items, if present. A score of ≥ 6 points is needed for the classification of GIANT CELL ARTERITIS.

1. Examination of the temporal artery showing absent or diminished pulse, tenderness, or hard 'cord-like' appearance.
2. Maximum erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) values prior to initiation of treatment for vasculitis.
3. Presence of either definitive vasculitis on temporal artery biopsy or halo sign on temporal artery ultrasound. There are no specific histopathologic criteria to define definitive vasculitis on temporal artery biopsy. Presence of giant cells, mononuclear leukocyte infiltration, and fragmentation of the internal elastic lamina were independently associated with histopathologic interpretation of definite vasculitis in the DCVAS cohort [24]. Halo sign is defined by the presence of an homogenous, hypoechoic wall thickening on ultrasound [25].
4. Bilateral axillary involvement is defined as luminal damage (stenosis, occlusion, or aneurysm) on angiography (computed tomography, magnetic resonance, or catheter-based) or ultrasound, halo sign on ultrasound, or fluorodeoxyglucose uptake on positron emission tomography.
5. Abnormal fluorodeoxyglucose (FDG) uptake in the arterial wall (e.g., greater than liver uptake by visual inspection) throughout the descending thoracic and abdominal aorta on positron emission tomography (PET).

Figure 1. The final 2022 American College of Rheumatology/EULAR Classification Criteria for Giant Cell Arteritis.

Table 2. Performance characteristics of the 2022 ACR/EULAR classification criteria for giant cell arteritis*

Patient subset	Total no. patients (no. GCA patients)	Sensitivity (95% CI)	Specificity (95% CI)	AUC (95% CI)
Development data set	1,054 (518)	84.8 (81.4–87.7)	95.0 (92.8–96.7)	0.90 (0.88–0.92)
Validation data set	451 (238)	87.0 (82.0–91.0)	94.8 (91.0–97.4)	0.91 (0.88–0.94)
Biopsy-proven GCA†	1,104 (355)	100.0 (99.0–100.0)	94.9 (93.1–96.4)	0.97 (0.97–0.98)
Large-vessel GCA‡	873 (124)	55.7 (46.5–64.6)	94.9 (93.1–96.4)	0.75 (0.71–0.80)

* Performance characteristics were tested in the subsets using the combined development and validation data sets to maximize sample size. ACR = American College of Rheumatology; GCA = giant cell arteritis; 95% CI = 95% confidence interval; AUC = area under the curve.
† Definite vasculitis on temporal artery biopsy (TAB).
‡ Involvement of the aorta or its branch arteries on imaging, without vasculitis on TAB.

The performance characteristics of the criteria in different subsets of patients with GCA are shown in Table 2 and Supplementary Appendix 20A (https://onlinelibrary.wiley.com/doi/10.1002/art.42325). Biopsy-proven GCA showed a sensitivity of 100% (95% CI 99.0–100.0%) and a specificity of 94.9% (95% CI 93.1–96.4%), and large-vessel GCA showed a sensitivity of 55.7% (95% CI 46.5–64.6%) and a specificity of 94.9% (93.1–96.4%). Sensitivity of the criteria in North America was 77.8% (95% CI 67.8–85.9%) and in Europe was 87.2% (95% CI 84.4–89.7%). Specificity in North America was 95.6% (95% CI 90.6–98.4%) and in Europe was 88.8% (95% CI 84.9–92.0%).

When the 1990 ACR classification criteria for GCA were applied to the DCVAS validation data set, the criteria performed poorly due to low sensitivity (80.3% [95% CI 74.6–85.1%]) but retained good specificity (92.5% [95% CI 88.1–95.7%]). In particular, the 1990 ACR criteria had poor sensitivity for patients with large-vessel GCA (37.1% [95% CI 28.6–46.2%]).

Age restrictions are absolute requirements for the 2022 ACR/EULAR classification criteria for GCA (≥50 years at diagnosis) and TAK (≤60 years at diagnosis). However, of the 70 patients with GCA diagnosed between the ages of 50 and 60 years, 44 (62.9%) met the new GCA classification criteria, 9 (12.9%) met the new TAK classification criteria, and only 2 (2.9%) met both the new GCA and TAK classification criteria (Supplementary Appendix 21, http://onlinelibrary.wiley.com/doi/10.1002/art.42325).

DISCUSSION

Presented here are the final 2022 ACR/EULAR GCA classification criteria. A 6-stage approach was used, underpinned by data from the multinational, prospective DCVAS study and informed by expert review and consensus at each stage. The comparator group for developing and validating the criteria were other vasculitides and conditions that mimic GCA, where discrimination from GCA is difficult but important. In the validation set, the new criteria had a sensitivity of 87.0% (95% CI 82.0–91.0%) and a specificity of 94.8% (95% CI 91.0–97.4%). These are the official final values that should be quoted when referring to the criteria. The sensitivity and specificity values calculated in the development set were very similar, providing reassurance that the statistical methods avoided overfitting of models. The new criteria incorporate modern imaging techniques and have excellent specificity and sensitivity within a large, international cohort of patients with GCA. The criteria were designed to have face and content validity for use in clinical trials and other research studies.

These criteria are validated and intended for the purpose of *classification* of vasculitis and are not appropriate for use to establish a *diagnosis* of vasculitis. The aim of the classification criteria is to differentiate cases of GCA from similar types of vasculitis in research settings (21). *Therefore, the criteria should only be applied when a diagnosis of large- or medium-vessel vasculitis has been made and all potential "vasculitis mimics" have been excluded*. The exclusion of mimics is a key aspect of many classification criteria including those for Sjögren's syndrome (22) and rheumatoid arthritis (16). The 1990 ACR classification criteria for vasculitis perform poorly when used for diagnosis (i.e., when used to differentiate between cases of vasculitis versus mimics without vasculitis) (23), and it is expected that the 2022 criteria would also perform poorly if used inappropriately as diagnostic criteria in people for whom alternative diagnoses, such as infection or other non-vasculitis inflammatory diseases, are still being considered.

The 2022 ACR/EULAR GCA classification criteria are the result of an incredibly large worldwide effort, in which an extensive set of data was collected from >1,000 patients with the submitted diagnosis of GCA. These criteria reflect current clinical practice, integrating different investigative methods (e.g., TAB, ultrasound, angiography, PET) from various countries and medical specialties. Real cases of GCA and comparators were reviewed by a wide range of experts in vasculitis to establish an unbiased diagnostic reference to derive the criteria. Advanced statistical methods including lasso logistic regression and cluster analyses were applied, which facilitated testing for different covariates of interest, namely specific patterns of vasculitic involvement in imaging. Modern classification techniques with weighted criterion with threshold scores were used, allowing for more discriminatory items to factor more heavily in disease classification.

When compared to the original 1990 ACR classification criteria for GCA, the 2022 ACR/EULAR GCA classification criteria

23265205, 0, Downloaded from https://onlinelibrary.wiley.com/doi/10.1002/art.42325, Wiley Online Library on [28/11/2022]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

demonstrated greater sensitivity while maintaining similar specificity to the 1990 criteria. In particular, the new criteria were able to correctly classify more patients with the large-vessel GCA subtype, in whom the sensitivity of the 1990 ACR criteria was only 37.1%. Unlike the 1990 ACR criteria, an age of ≥50 years at diagnosis is a mandatory requirement to classify GCA in the 2022 ACR/EULAR criteria. This age threshold included >99% of patients with the reference diagnosis of GCA. The new criteria maintain good discriminative ability for patients diagnosed between the ages of 50 and 60 years, the interval where the absolute age requirements for the 2022 ACR/EULAR criteria for GCA and for TAK can overlap.

A potential limitation of these criteria was the nonstandardized acquisition of clinical and imaging data among patients with LVV and comparators (e.g., not all patients underwent vascular examination of the temporal arteries, PET was not available in many centers treating patients with LVV, and TAB and/or ultrasound was not performed in all patients with suspected GCA, etc.). However, this reflects existing differences in clinical practice, and the 11 items included in the criteria allow for a feasible evaluation of patients in any clinical setting. These criteria also provide flexibility for classifying a patient, regardless of the diagnostic assessment strategy employed by physicians. Definite vasculitis on TAB was defined by the submitting physician and did not undergo central review; ~20% of cases did not have specific histopathologic findings but were reported as "definitive vasculitis on TAB" alone. Most patients were recruited from Europe and North America, with fewer patients from Asia and Oceania. The performance characteristics of the criteria should be further tested in other populations that were underrepresented in the DCVAS cohort and may have different clinical presentations of GCA.

The 2022 ACR/EULAR classification criteria for GCA are the product of a rigorous methodologic process that utilized an extensive data set generated by the work of a remarkable international group of collaborators. These criteria have been endorsed by the ACR and EULAR and are now ready for use in clinical research.

ACKNOWLEDGMENTS

We acknowledge the patients and clinicians who provided data to the DCVAS project.

2022 American College of Rheumatology/European Alliance of Associations for Rheumatology Classification Criteria for Granulomatosis With Polyangiitis

Joanna C. Robson,[1] Peter C. Grayson,[2] Cristina Ponte,[3] Ravi Suppiah,[4] Anthea Craven,[5] Andrew Judge,[6] Sara Khalid,[5] Andrew Hutchings,[7] Richard A. Watts,[8] Peter A. Merkel,[9] and Raashid A. Luqmani[5]

This criteria set has been approved by the American College of Rheumatology (ACR) Board of Directors and the European Alliance of Associations for Rheumatology (EULAR) Executive Committee. This signifies that the criteria set has been quantitatively validated using patient data, and it has undergone validation based on an independent data set. All ACR/EULAR-approved criteria sets are expected to undergo intermittent updates.

The ACR is an independent, professional, medical and scientific society that does not guarantee, warrant, or endorse any commercial product or service.

Objective. To develop and validate revised classification criteria for granulomatosis with polyangiitis (GPA).

Methods. Patients with vasculitis or comparator diseases were recruited into an international cohort. The study proceeded in 5 phases: 1) identification of candidate criteria items using consensus methodology, 2) prospective collection of candidate items present at the time of diagnosis, 3) data-driven reduction of the number of candidate items, 4) expert panel review of cases to define the reference diagnosis, and 5) derivation of a points-based risk score for disease classification in a development set using least absolute shrinkage and selection operator logistic regression, with subsequent validation of performance characteristics in an independent set of cases and comparators.

Results. The development set for GPA consisted of 578 cases of GPA and 652 comparators. The validation set consisted of an additional 146 cases of GPA and 161 comparators. From 91 candidate items, regression analysis identified 26 items for GPA, 10 of which were retained. The final criteria and their weights were as follows: bloody nasal discharge, nasal crusting, or sino-nasal congestion (+3); cartilaginous involvement (+2); conductive or sensorineural hearing loss (+1); cytoplasmic antineutrophil cytoplasmic antibody (ANCA) or anti–proteinase 3 ANCA positivity (+5); pulmonary nodules, mass, or cavitation on chest imaging (+2); granuloma or giant cells on biopsy (+2); inflammation or consolidation of the nasal/paranasal sinuses on imaging (+1); pauci-immune glomerulonephritis (+1); perinuclear ANCA or antimyeloperoxidase ANCA positivity (−1); and eosinophil count ≥1 × 10^9/liter (−4). After excluding mimics of vasculitis, a patient with a diagnosis of small- or medium-vessel vasculitis could be classified as having GPA if the cumulative score was ≥5 points. When these criteria were tested in the validation data set, the sensitivity was 93% (95% confidence interval [95% CI] 87–96%) and the specificity was 94% (95% CI 89–97%).

Conclusion. The 2022 American College of Rheumatology/European Alliance of Associations for Rheumatology classification criteria for GPA demonstrate strong performance characteristics and are validated for use in research.

This article is published simultaneously in the March 2022 issue of *Annals of the Rheumatic Diseases*.

The Diagnostic and Classification Criteria in Vasculitis (DCVAS) study, of which the development of these classification criteria was a part, was funded by grants from the American College of Rheumatology (ACR), the European Alliance of Associations for Rheumatology (EULAR), the Vasculitis Foundation, and the University of Pennsylvania Vasculitis Center.

INTRODUCTION

The antineutrophil cytoplasmic antibody (ANCA)–associated vasculitides (AAV) are multisystem disorders involving inflammation of the small blood vessels and include granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis (EGPA) (1). GPA is characterized by necrotizing granulomatous inflammation involving the ears, nose, and upper and lower respiratory tracts, and necrotizing vasculitis affecting predominantly small- to medium-sized vessels, often including necrotizing glomerulonephritis (1).

Unlike diagnostic criteria, the purpose of classification criteria is to ensure that a homogeneous population is selected for inclusion in clinical trials and other research studies of GPA. In 1990, the American College of Rheumatology (ACR) published criteria for the classification of GPA (then named Wegener's granulomatosis) (2–4). The 1990 criteria were effective and widely accepted, facilitating coordinated approaches to international randomized controlled trials (5,6). In 2011 it was proposed to change the name "Wegener's granulomatosis" to "granulomatosis with polyangiitis" with subsequent wide adoption of the new terminology (7–9). The 1994 and 2012 publications of the international Chapel Hill Consensus Conference (CHCC) nomenclature for vasculitis clarified and standardized the nomenclature of the systemic vasculitides (1,10). The CHCC is a nomenclature system based on expert consensus rather than a classification system (1).

There are several important reasons for the development of revised classification criteria for the vasculitides, including a decline in the sensitivity of the 1990 ACR classification criteria, particularly for AAV (11); a consensus that any such criteria must now incorporate testing for ANCA; increased and widespread use, since 1990, of cross-sectional diagnostic imaging tools, including magnetic resonance imaging and computed tomography (12,13); and the introduction and adoption of the classification of patients with MPA, a term not in use in the 1990 ACR classification criteria.

There have been methodologic advances in the derivation of classification criteria, moving from the "number of criteria" rule, as used in the ACR 1990 criteria (3), toward weighted criteria with threshold scores, as demonstrated in the 2010 classification criteria for rheumatoid arthritis (14). Weighted criteria improve measurement properties of classification criteria because certain items within a criteria list may be more discriminative. The previous 1990 criteria for vasculitis collected retrospective data from patient files, without specification of which items were relevant at the time of diagnosis compared to those that were important later in the disease process. Criteria based on prospectively collected data sets from newly diagnosed patients should have higher face validity as inclusion criteria for future clinical trials of early-stage disease. This article outlines the development and validation of the revised ACR/European Alliance of Associations for Rheumatology (EULAR)–endorsed classification criteria for GPA.

METHODS

A detailed and complete description of the methods involved in the development and validation of the classification criteria for GPA is provided in Supplementary Appendix 1, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41986/abstract. Briefly, an international Steering Committee comprising clinician investigators with expertise in vasculitis, statisticians, and data managers was established to oversee the overall Diagnostic and Classification Criteria in Vasculitis (DCVAS) project (15). The Steering Committee established a 5-stage plan using data-driven and consensus methodology to develop the criteria for each of 6 forms of vasculitis.

Stage 1: generation of candidate classification items for the systemic vasculitides. Candidate classification items were generated by expert opinion and reviewed by a group of vasculitis experts across a range of specialties using a nominal group technique.

Stage 2: DCVAS prospective observational study. A prospective, international, multisite observational study was conducted (see Appendix A for study investigators and sites). Ethical approval was obtained from national and local ethics committees. Consecutive patients representing the full spectrum of disease were recruited from academic and community practices. Patients were included if they were 18 years or older and had a diagnosis of vasculitis or a condition that mimics vasculitis. Patients with AAV could only be enrolled within 2 years of diagnosis. Only data present at diagnosis were recorded.

Stage 3: refinement of candidate items specifically for AAV. The Steering Committee conducted a data-driven process to reduce the number of candidate items of relevance to cases and comparators for AAV. Items were selected for exclusion if they had a prevalence of <5% within the data set and/or they were not clinically relevant for classification criteria (e.g., related to infection, malignancy, or demographic characteristics). Low-frequency items of clinical importance could be combined, when appropriate.

Submitted for publication February 28, 2020; accepted in revised form September 21, 2021.

Stage 4: expert review to derive a gold standard–defined set of cases of AAV. Experts in vasculitis from a wide range of geographic locations and specialties reviewed all submitted cases of vasculitis and a random selection of mimics of vasculitis. Each reviewer was asked to review ~50 submitted cases to confirm the diagnosis and to specify the certainty of their diagnosis as follows: very certain, moderately certain, uncertain, or very uncertain. Only cases agreed upon with at least moderate certainty were retained for further analysis.

Stage 5: derivation and validation of the final classification criteria for GPA. The DCVAS AAV data set was randomly split into development (80%) and validation (20%) sets. Comparisons were performed between cases of GPA confirmed by expert review and a comparator group randomly selected from the DCVAS cohort in the following proportions: another type of AAV (including MPA and EGPA), 64%; another form of small-vessel vasculitis (e.g., cryoglobulinemic vasculitis) or medium-vessel vasculitis (e.g., polyarteritis nodosa), 36%. Least absolute shrinkage and selection operator (lasso) logistic regression was used to identify items from the data set and create a parsimonious model including only the most important items. The final items in the model were formulated into a clinical risk-scoring tool with each factor assigned a weight based on its respective regression coefficient. A threshold that best balanced sensitivity and specificity was identified for classification.

In sensitivity analyses, the final classification criteria were applied to an unselected population of cases and comparators from the DCVAS data set based on the submitting physician diagnosis. Comparison was also made between the measurement properties of the new classification criteria for GPA and the 1990 ACR classification criteria for GPA using pooled data from the development and validation sets.

RESULTS

Generation of candidate classification items for the systemic vasculitides. The Steering Committee identified >1,000 candidate items for the DCVAS case report form (see Supplementary Appendix 2, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41986/abstract).

DCVAS prospective observational study. Between January 2011 and December 2017, the DCVAS study recruited 6,991 participants from 136 sites in 32 countries. Information on the DCVAS sites, investigators, and study participants is listed in Supplementary Appendices 3, 4, and 5, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41986/abstract.

Refinement of candidate items specifically for AAV. Following a data-driven and expert consensus process, 91 items from the DCVAS case report form were retained for regression analysis, including 45 clinical (14 composite), 18 laboratory (2 composite), 12 imaging (all composite), and 16 biopsy (1 composite) items. Some clinical items were removed in favor of similar but more specific pathophysiologic descriptors. Supplementary Appendix 6, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41986/abstract, lists the final candidate items used in the derivation of the classification criteria for GPA, MPA, and EGPA.

Expert review to derive a gold standard–defined final set of cases of AAV. Fifty-five independent experts reviewed vignettes derived from the case report forms for 2,871 cases submitted with a diagnosis of either small-vessel vasculitis

Table 1. Demographic and disease features of cases of GPA and comparators*

	GPA (n = 724)	Comparators (n = 813)†	*P*
Age, mean ± SD years	53.6 ± 16.2	56.4 ± 17.1	0.001
Sex, no. (%) female	340 (47.0)	424 (52.2)	0.048
Maximum serum creatinine, mean			0.077
μmoles/liter	168.3	185.2	
mg/dl	1.9	2.1	
cANCA positive, no. (%)	531 (73.3)	40 (4.9)	<0.001
pANCA positive, no. (%)	71 (9.8)	342 (42.1)	<0.001
Anti–PR3-ANCA positive, no. (%)	595 (82.2)	21 (2.6)	<0.001
Anti–MPO-ANCA positive, no. (%)	59 (8.1)	399 (49.1)	<0.001
Maximum eosinophil count ≥1 × 10^9/liter, no. (%)	196 (27)	366 (45)	<0.001

* cANCA = cytoplasmic antineutrophil cytoplasmic antibody; pANCA = perinuclear ANCA; anti–PR3-ANCA = anti–proteinase 3–ANCA; anti–MPO-ANCA = anti–myeloperoxidase-ANCA.
† Diagnoses of comparators for the classification criteria for granulomatosis with polyangiitis (GPA) included microscopic polyangiitis (n = 291), eosinophilic granulomatosis with polyangiitis (n = 226), polyarteritis nodosa (n = 51), non–ANCA-associated small-vessel vasculitis that could not be subtyped (n = 51), Behçet's disease (n = 50), IgA vasculitis (n = 50), cryoglobulinemic vasculitis (n = 34), ANCA-associated vasculitis that could not be subtyped (n = 25), primary central nervous system vasculitis (n = 19), and anti–glomerular basement membrane disease (n = 16).

(90% of case report forms) or another type of vasculitis or a mimic of vasculitis (10% of case report forms). The characteristics of the expert reviewers are shown in Supplementary Appendix 7, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41986/abstract. A flow chart showing the results of the expert review process is shown in Supplementary Appendix 8, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41986/abstract. A total of 2,072 cases (72%) passed the process and were designated as cases of vasculitis; these cases were used for the stage 5 analyses.

After expert review, 724 of 843 cases retained a reference diagnosis of GPA. There were 813 comparators randomly selected for analysis. Table 1 shows the demographic and disease features of the 1,537 cases included in this analysis (724 patients with GPA and 813 comparators), of which 1,230 (80%, 578 patients with GPA and 652 comparators) were in the development set, and 307 (20%, 146 patients with GPA and 161 comparators) were in the validation set.

Derivation and validation of the final classification criteria for GPA. Lasso logistic regression analysis using all 91 items resulted in a model of 26 independent items (see Supplementary Appendix 9B, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41986/abstract). The variables "positive test for cytoplasmic ANCA (cANCA)" and "positive test for anti–proteinase 3 (anti-PR3)

2022 AMERICAN COLLEGE OF RHEUMATOLOGY / EUROPEAN ALLIANCE OF ASSOCIATIONS FOR RHEUMATOLOGY

CLASSIFICATION CRITERIA FOR **GRANULOMATOSIS WITH POLYANGIITIS**

CONSIDERATIONS WHEN APPLYING THESE CRITERIA

- **These classification criteria should be applied to classify a patient as having granulomatosis with polyangiitis when a diagnosis of small- or medium-vessel vasculitis has been made**
- **Alternate diagnoses mimicking vasculitis should be excluded prior to applying the criteria**

CLINICAL CRITERIA

Nasal involvement: bloody discharge, ulcers, crusting, congestion, blockage, or septal defect / perforation	+3
Cartilaginous involvement (inflammation of ear or nose cartilage, hoarse voice or stridor, endobronchial involvement, or saddle nose deformity)	+2
Conductive or sensorineural hearing loss	+1

LABORATORY, IMAGING, AND BIOPSY CRITERIA

Positive test for cytoplasmic antineutrophil cytoplasmic antibodies (cANCA) or antiproteinase 3 (anti-PR3) antibodies	+5
Pulmonary nodules, mass, or cavitation on chest imaging	+2
Granuloma, extravascular granulomatous inflammation, or giant cells on biopsy	+2
Inflammation, consolidation, or effusion of the nasal/paranasal sinuses, or mastoiditis on imaging	+1
Pauci-immune glomerulonephritis on biopsy	+1
Positive test for perinuclear antineutrophil cytoplasmic antibodies (pANCA) or antimyeloperoxidase (anti-MPO) antibodies	-1
Blood eosinophil count ≥ 1 x10^9/liter	-4

Sum the scores for 10 items, if present. A score of ≥ 5 is needed for classification of GRANULOMATOSIS WITH POLYANGIITIS.

Figure 1. 2022 American College of Rheumatology/European Alliance of Associations for Rheumatology classification criteria for granulomatosis with polyangiitis.

antibody" and the variables "positive test for perinuclear ANCA (pANCA)" and "positive test for antimyeloperoxidase (anti-MPO) antibody" were strongly colinear and were combined within the model as "positive test for cANCA or positive test for anti-PR3 antibody" and "positive test for pANCA or positive test for anti-MPO antibody," respectively. Each item was scrutinized for inclusion based on statistical significance, clinical relevance, and specificity to GPA, resulting in 10 final items. Weighting of an individual criterion was based on logistic regression fitted to the 10 selected items (see Supplementary Appendix 10B, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41986/abstract).

Model performance. Use of a cutoff of ≥5 for total risk score (see Supplementary Appendix 11B, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41986/abstract, for different cut points) yielded a sensitivity of 92.5% (95% confidence interval [95% CI] 86.9–96.2%) and a specificity of 93.8% (95% CI 88.9–97.0%) in the validation set. The area under the curve (AUC) for the model was 0.98 (95% CI 0.98–0.99) in the development set and 0.99 (95% CI 0.98–1.00) in the validation set (Supplementary Appendix 12B, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41986/abstract). The final classification criteria for GPA are shown in Figure 1 (for the slide presentation version, see Supplementary Figure 1, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41986/abstract).

Sensitivity analyses. The classification criteria for GPA were applied to 2,511 patients randomly selected from the DCVAS database using the original physician-submitted diagnosis (n = 483 GPA and 2,028 comparators). Use of the same cut point of ≥5 points for the classification of GPA yielded a similar specificity of 94.6% but a lower sensitivity of 83.8%. This upheld the a priori hypothesis that specificity would remain unchanged but sensitivity would be reduced in a population with fewer clear-cut diagnoses of GPA (i.e., cases that did not pass expert review).

When the 1990 ACR classification criteria for GPA were applied to the DCVAS data set, the criteria performed poorly due to low sensitivity (69.3%) and moderate specificity (75.8%), with an AUC of 0.73 (95% CI 0.70–0.75).

DISCUSSION

Presented here are the final 2022 ACR/EULAR GPA classification criteria. A 5-stage approach has been used, underpinned by data from the multinational prospective DCVAS study and informed by expert review and consensus at each stage. The comparator group for developing and validating the criteria were other forms of AAV and other small- and medium-vessel vasculitides, the clinical entities where discrimination from GPA is difficult, but important. The new criteria for GPA have excellent sensitivity and specificity and incorporate ANCA testing and modern imaging techniques. The criteria were designed to have face and content validity for use in clinical trials and other research studies.

These criteria are validated and intended for the purpose of *classification* of vasculitis and are not appropriate for use in establishing a *diagnosis* of vasculitis. The aim of the classification criteria is to differentiate cases of GPA from similar types of vasculitis in research settings. Therefore, the criteria should only be applied when a diagnosis of small- or medium-vessel vasculitis has been made and all potential "vasculitis mimics" have been excluded. The exclusion of mimics is a key aspect of many classification criteria, including those for Sjögren's syndrome (16) and rheumatoid arthritis (14). The 1990 ACR classification criteria for vasculitis perform poorly when used for diagnosis (i.e., when used to differentiate between cases of vasculitis versus mimics without vasculitis) (17), and it is expected that the 2022 criteria would also perform poorly if used inappropriately as diagnostic criteria in people in whom alternative diagnoses, such as infection or other non-vasculitis inflammatory diseases, are still being considered. The relatively low weight assigned to glomerulonephritis in these classification criteria highlights the distinction between classification and diagnostic criteria. While detection of kidney disease is important to diagnose GPA, glomerulonephritis is common among patients with either GPA or MPA and thus does not function as a strong classifier between these conditions.

These criteria differ from the previous 1990 ACR criteria in that they have been developed using cases presenting prospectively at the start of their disease process. This approach is different from the methods used to generate the 1990 ACR criteria, in which prevalent case records were utilized, potentially including items related to irreversible damage accrued over time. Inclusion of newly diagnosed cases in these criteria should improve their accuracy within the context of early intervention trials as well as refractory disease. The comparators used for these new criteria are also more appropriate and are closer mimics of GPA; for example, comparators with predominantly small-vessel vasculitis rather than predominantly giant cell arteritis were included. The new criteria perform better than previous criteria within this data set (11). ANCA is a major discriminator within these criteria, although patients can be classified as having GPA without having a positive test result for ANCA if they have a sufficient number of other features. These new criteria were validated in an independent data set and are weighted with threshold scores (14,16) to maximize predictive ability.

There are some study limitations to consider. Although this was the largest international study ever conducted in vasculitis, most patients were recruited from Europe, Asia, and North America. The performance characteristics of the criteria should be further tested in African and South American populations, which may have different clinical presentations of vasculitis. These

criteria were developed using data collected from adult patients with vasculitis. Although the clinical characteristics of GPA and the other vasculitides which these criteria were tested against are not known to differ substantially between adults and children, these criteria should be applied to children with some caution. The scope of the criteria is intentionally narrow and applies only to patients who have been diagnosed as having vasculitis. Diagnostic criteria are not specified. The criteria are intended to identify homogeneous populations of disease and, therefore, may not be appropriate for studies focused on the full spectrum of clinical heterogeneity in these conditions. To maximize relevance and face validity of the new criteria, study sites and expert reviewers were recruited from a broad range of countries and different medical specialties. Nonetheless, the majority of patients were recruited from academic rheumatology or nephrology units, which could have introduced referral bias.

A key strength of this study is the use of an independent expert review process to confirm cases of GPA and comparators to avoid the circularity of using predefined criteria to define the gold standard. Approximately one-quarter of cases were excluded via this process, due to either a lack of consensus on exact diagnosis or insufficient data available to make the diagnosis. A limitation of this approach, however, could be the exclusion of true, but less clearcut, cases submitted by the original physicians. It is important that cases are classified accurately for inclusion in clinical trials; therefore, some loss of sensitivity may be appropriate. Importantly, this study also demonstrated that applying the new criteria for GPA to the whole unselected DCVAS data set resulted in a reduction in sensitivity while maintaining specificity. Thus, the criteria should also be useful in a more generalized, "real-world" population.

The 2022 ACR/EULAR classification criteria for GPA are the product of a rigorous methodologic process that utilized an extensive data set generated by the work of a remarkable international group of collaborators. These criteria have been endorsed by the ACR and EULAR and are now ready for use to differentiate one type of vasculitis from another to define populations in research studies.

Guidelines and recommendations developed and/or endorsed by the American College of Rheumatology (ACR) are intended to provide guidance for patterns of practice and not to dictate the care of a particular patient. The ACR considers adherence to the recommendations within this guideline to be voluntary, with the ultimate determination regarding their application to be made by the physician in light of each patient's individual circumstances. Guidelines and recommendations are intended to promote beneficial or desirable outcomes but cannot guarantee any specific outcome. Guidelines and recommendations developed and endorsed by the ACR are subject to periodic revision as warranted by the evolution of medical knowledge, technology, and practice. ACR recommendations are not intended to dictate payment or insurance decisions, and drug formularies or other third-party analyses that cite ACR guidelines should state this. These recommendations cannot adequately convey all uncertainties and nuances of patient care.

The ACR is an independent, professional, medical and scientific society that does not guarantee, warrant, or endorse any commercial product or service.

Objective. To provide evidence-based recommendations and expert guidance for the management of Kawasaki disease (KD), focusing on clinical scenarios more commonly addressed by rheumatologists.

Methods. Sixteen clinical questions regarding diagnostic testing, treatment, and management of KD were developed in the Patient/Population, Intervention, Comparison, and Outcomes (PICO) question format. Systematic literature reviews were conducted for each PICO question. We used the Grading of Recommendations, Assessment, Development and Evaluation method to assess the quality of evidence and formulate recommendations. Each recommendation required consensus from at least 70% of the Voting Panel.

Results. We present 1 good practice statement, 11 recommendations, and 1 ungraded position statement to guide the management of KD and clinical scenarios of suspected KD. These recommendations for KD are focused on situations in which input from rheumatologists may be requested by other managing specialists, such as in cases of treatment-refractory, severe, or complicated KD. The good practice statement affirms that all patients with KD should receive initial treatment with intravenous immunoglobulin (IVIG). In addition, we developed 7 strong and 4 conditional recommendations for the management of KD or suspected KD. Strong recommendations include prompt treatment of incomplete KD, treatment with aspirin, and obtaining an echocardiogram in the setting of unexplained macrophage activation syndrome or shock. Conditional recommendations include use of IVIG with other adjuvant agents for patients with KD and high-risk features of IVIG resistance and/or coronary artery aneurysms. These recommendations endorse minimizing risk to the patient by using established therapy promptly at disease onset and identifying situations in which adjunctive therapy may be warranted.

Conclusion. These recommendations provide guidance regarding diagnostic strategies, use of pharmacologic agents, and use of echocardiography in patients with suspected or confirmed KD.

INTRODUCTION

Kawasaki disease (KD) is a medium vessel vasculitis as presented in the Chapel Hill Consensus Conference nomenclature system (1). It is 1 of 2 primary common vasculitis syndromes that predominantly affect children (the other being IgA vasculitis [Henoch-Schönlein]). KD is seen with relative frequency in young children, at an incidence rate of 25–50 cases per 100,000 persons per year in the US, similar to that of type 1 diabetes (2,3). It typically presents in children <5 years of age as an acute, self-limited febrile disease and is characterized by a combination of several characteristic clinical signs, which include polymorphic rash, nonpurulent conjunctival injection, oropharyngeal and lip mucositis, tongue papillitis, erythema and edema of the hands and feet, as well as unilateral cervical lymphadenopathy.

From a histopathologic perspective, KD is characterized by aggressive neutrophil-mediated panmural vascular necrosis without granuloma formation, followed by intimal hyperplasia and subacute lymphocytic inflammation in advanced disease. It primarily affects the coronary arteries but can also affect medium-caliber arteries throughout the body (4). Therefore, it shares some features with polyarteritis nodosa, and prior to the recognition of KD as a distinct entity, infants with fatal fulminant forms of KD were considered to have "infantile polyarteritis nodosa" (5).

When treated appropriately, KD is associated with a low mortality rate (~0.08% case fatality rate in the largest reported series) (6). However, in the developed world, it is the most common cause of acquired cardiac disease in childhood, with 25% of untreated patients and 5% of treated patients developing coronary artery aneurysms. Among infants <6 months of age, the risk of a coronary artery aneurysm is 50%, even in KD patients who received treatment with intravenous immunoglobulin (IVIG) within the first 10 days of illness (7).

Given increasing options available to treat systemic vasculitis, the American College of Rheumatology (ACR) and Vasculitis Foundation supported the development of guidelines for the management of large, medium, and small vessel vasculitis. This guideline presents evidence-based recommendations for the diagnostic testing, treatment, and management of KD. Recognizing the comprehensive guidelines developed by the American Heart Association (AHA) for the management of KD (3), the guideline focuses on clinical management questions that are generally posed to rheumatologists, such as the use of adjunctive therapies for initial treatment of severe disease and treatment approaches for refractory disease. Although this guideline may inform an international audience, these recommendations were developed considering experience with and availability of treatment and diagnostic options in the US.

METHODS

This guideline followed the ACR guideline development process (https://www.rheumatology.org/Practice-Quality/Clinical-Support/Clinical-Practice-Guidelines) using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) methodology to rate the quality of evidence and develop recommendations (8,9). ACR policy guided the management of conflicts of interest and disclosures (https://www.rheumatology.org/Practice-Quality/Clinical-Support/Clinical-Practice-Guidelines/Vasculitis). Supplementary Appendix 1 (available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.42041/abstract) presents a detailed description of the methods.

Sixteen clinical questions addressing the diagnostic testing, treatment, and management of KD were developed by the Core Team, initial Voting Panel, and Expert Panel in the Patient/Population, Intervention, Comparison, and Outcomes (PICO) format. The Literature Review Team undertook systematic literature reviews

for prespecified PICO questions. The Expert Panel, including rheumatologists and a pediatric cardiologist, provided expert knowledge to inform discussion of the PICO questions and findings of the literature review. This study did not involve human subjects, and therefore, approval from Human Studies Committees was not required.

The initial Voting Panel comprised 9 adult rheumatologists (SAC, AMA, DLC, PCG, PAM, RLR, PS, JHS, AW), 5 pediatric rheumatologists (LFI, SK, SS, MFI, RPS), and 2 patients (KAF, OIV). They reviewed the Literature Review Team's evidence summaries and formulated and voted on an initial set of recommendations. To incorporate broader expertise from the pediatric community and validate the results from the initial Voting Panel, a second Voting Panel was established and comprised 8 pediatric rheumatologists new to the Voting Panel (MG, KA, BAB, KH, SKL, MBS, HVM, CY-T), 4 pediatric rheumatologists who participated in both Voting Panels (LFI, SK, SS, RPS), a pediatric infectious disease physician with extensive expertise in KD (AHT), and a pediatric cardiologist with extensive expertise in KD (KF). The second Voting Panel also reviewed the Literature Review Team's findings and independently formulated and voted on recommendations. Members of the second Voting Panel who were not on the initial Voting Panel were not provided with the recommendations formulated by the initial Voting Panel prior to the second panel's voting. Each recommendation required consensus from at least 70% of the Voting Panel.

How to interpret the recommendations

A *strong* recommendation is typically supported by moderate- to high-quality evidence (e.g., multiple randomized controlled trials). For a strong recommendation, the recommended course of action would apply to all or almost all patients. Only a small proportion of clinicians/patients would not want to follow the recommendation. For example, an intervention may be strongly recommended if it is considered low-cost, without harms, and the consequence of not performing the intervention may be catastrophic. An intervention may be strongly recommended against if there is high certainty that the intervention will lead to more harm than the comparison with very low or low certainty about its benefit (10).

A *conditional* recommendation is generally supported by lower-quality evidence or a close balance between desirable and undesirable outcomes. For a conditional recommendation, the recommended course of action would apply to the majority of patients, but the alternative is a reasonable consideration. Conditional recommendations always warrant a shared decision-making approach. We specify conditions under which the alternative may be considered.

In one instance, the committee found that the evidence for a particular PICO question did not support a graded recommendation, and the Voting Panel did not favor one intervention over another. However, the Voting Panel believed the PICO question addressed a commonly encountered clinical question, and thus felt that providing guidance for this question was warranted. For this situation, we present an "ungraded position statement" which reflects general views of the Voting Panel.

In this evidence-based guideline, we explicitly used the best evidence available and present it in a transparent manner for the clinician reader/user (10). In some instances, this includes randomized trials in which the interventions under consideration are directly compared. The GRADE system rates evidence that

Table 1. Definitions of selected terms used in the recommendations/ungraded position statements for KD*

Term	Definition
Disease states	
KD	Fever lasting at least 5 days without any other explanation with at least 4 of the 5 following principal clinical findings: 1) bilateral bulbar conjunctival injection without exudate, 2) erythema and cracking of lips, strawberry tongue, and/or erythema of oral and pharyngeal mucosa, 3) erythema and edema of the hands or feet (acute phase), and/or periungual desquamation (subacute phase), 4) maculopapular, diffuse erythroderma, or erythema multiforme–like rash, or 5) cervical lymphadenopathy (at least 1 lymph node >1.5 cm in diameter), usually unilaterally. The diagnosis may be made with only 4 days of fever if ≥4 principal clinical findings are present.
Incomplete KD	Prolonged unexplained fever in an infant or child with <4 of the principal clinical findings of KD (see above), and compatible laboratory markers (elevated ESR/CRP level, elevated transaminase levels, UA with leukocyte esterase–negative WBCs) or echocardiographic findings (coronary artery dilatation), defined according to the algorithm in references 3 and 31
Acute KD	Initial febrile phase of KD
Medications	
IVIG	Single dose of 2 gm/kg (no defined maximum dose, but the reasonable maximum range is 100–140 gm)
Nonglucocorticoid immunomodulatory therapy	Anakinra, cyclosporine, or infliximab
Glucocorticoids	Prednisone 2 mg/kg/day (maximum dose 60 mg/day) tapered over 15 days, or equivalent
Aspirin	High dose: 80–100 mg/kg/day; moderate dose: 30–50 mg/kg/day; low dose: 3–5 mg/kg/day

* KD = Kawasaki disease; ESR = erythrocyte sedimentation rate; CRP = C-reactive protein; UA = uric acid; WBCs = white blood cells; IVIG = intravenous immunoglobulin.

comes exclusively from the collective experience of the Voting Panel and Patient Panel members as "very low–quality" evidence.

For each recommendation, details regarding the PICO questions and the GRADE evidence tables can be found in Supplementary Appendix 2 (http://onlinelibrary.wiley.com/doi/10.1002/art.42041/abstract).

RESULTS

For the evidence report, the Literature Review Team summarized 275 articles to address 16 PICO questions for KD. Details regarding the methods utilized for the literature review are provided in Supplementary Appendix 1 (http://onlinelibrary.wiley.com/doi/10.1002/art.42041/abstract). Both the initial and second Voting Panel utilized the evidence report to formulate their recommendations. The recommendations formulated by the second Voting Panel were consistent with those of the initial Voting Panel. Clinical considerations for the recommendations were further expanded by the second Voting Panel, and thus the recommendations of the second Voting Panel are presented here.

Table 1 presents definitions of selected terms used in the recommendations, and Table 2 presents the recommendations with their supporting PICO questions and level of evidence. Figure 1 shows a schematic highlighting the key recommendations for the treatment of KD. Conditional recommendations are indicated as such and are generally conditional due to a lack of high-quality evidence (e.g., multiple randomized controlled trials) supporting the recommendation.

Treatment recommendations

Good Practice Statement: IVIG is the standard-of-care therapy for the initial treatment of KD.

IVIG has been established as the standard-of-care treatment for KD for the last 4 decades due to the significant reduction in the rate of coronary artery aneurysms as well as a reduction in the duration of fever and other symptoms associated with its use (11). Although no comparative trials of IVIG and glucocorticoids have been conducted, glucocorticoids alone were considered inadequate to treat KD based on findings from an early case series (12,13). Thus, IVIG use is a mainstay of KD therapy. The mechanisms of the therapeutic effect of IVIG in KD are still under study (14).

Recommendation: For patients with acute KD who are at high risk of IVIG resistance or developing coronary artery aneurysms, use of IVIG with adjunctive glucocorticoids as initial therapy is conditionally recommended over treatment with IVIG alone.

Risk scores have been developed to identify patients at high risk of IVIG resistance in Japanese populations, but these scores had poor sensitivity and specificity in a multiethnic US population (15–17). A recent study of patients in North America identified the following demographic and clinical characteristics as predictors for the development of coronary artery aneurysms at 2–8 weeks: a Z score in the left anterior descending or right coronary artery of ≥2.0, age <6 months, Asian race, and a C-reactive protein level of ≥13 mg/dl (18). In the US, features that suggest an increased likelihood of morbidity in KD include age <6 months or >9 years at diagnosis (19,20). In patients with giant aneurysms (Z score >10) or multiple aneurysms, regression of the aneurysms (via remodeling) at late stages (21) is less likely, and large aneurysms are associated with the greatest morbidity rate (21,22).

Emerging evidence suggests that adding glucocorticoids to IVIG as primary therapy can decrease the risk of developing coronary artery aneurysms, although the strongest evidence is from a Japanese population (16). There is also emerging evidence that the addition of glucocorticoids can decrease the progression of coronary artery aneurysms in patients with coronary aneurysms at the time of diagnosis (23,24).

Thus, the use of glucocorticoids with IVIG is a treatment option in patients who are at high risk of coronary artery aneurysms. For this recommendation, the Voting Panel defined high-risk features as a Z score of ≥2.5 (25–27) for the left anterior descending or right coronary artery at the time of the initial echocardiography and age <6 months. This definition uses the Z score of 2.5 instead of 2.0, since a score of 2.5 is defined as representing a true aneurysm. We also do not include patients >9 years of age, as only a portion of these patients are believed to be "high-risk." The Voting Panel acknowledges that further investigation clarifying the features of "high-risk" KD in a US population is needed. Optimal dosing and duration of glucocorticoids are still to be determined and will require further study in a US population, but a typical dosage would be prednisone starting at 2 mg/kg/day (maximum 60 mg/day), with the dose tapered over 15 days. The use of IVIG alone is conditionally recommended when the treating physician is unsure whether a patient is at high risk of developing coronary artery aneurysms, or when additional glucocorticoid exposure may be detrimental to the patient. The use of glucocorticoids is generally *not* recommended in patients who do not have features suggestive of high risk.

Recommendation: For patients with acute KD who are at high risk of IVIG resistance or developing coronary artery aneurysms, using IVIG with other nonglucocorticoid immunomodulatory immunosuppressive agents as initial therapy is conditionally recommended over treatment with IVIG alone.

For patients with features of high-risk disease, adjunctive therapy with a nonglucocorticoid immunomodulatory agent, such as infliximab, anakinra, or cyclosporine, may improve outcomes in acute disease and may also improve cardiac outcomes

Table 2. Good practice statement, recommendations, and ungraded position statement regarding diagnostic testing for and treatment of KD*

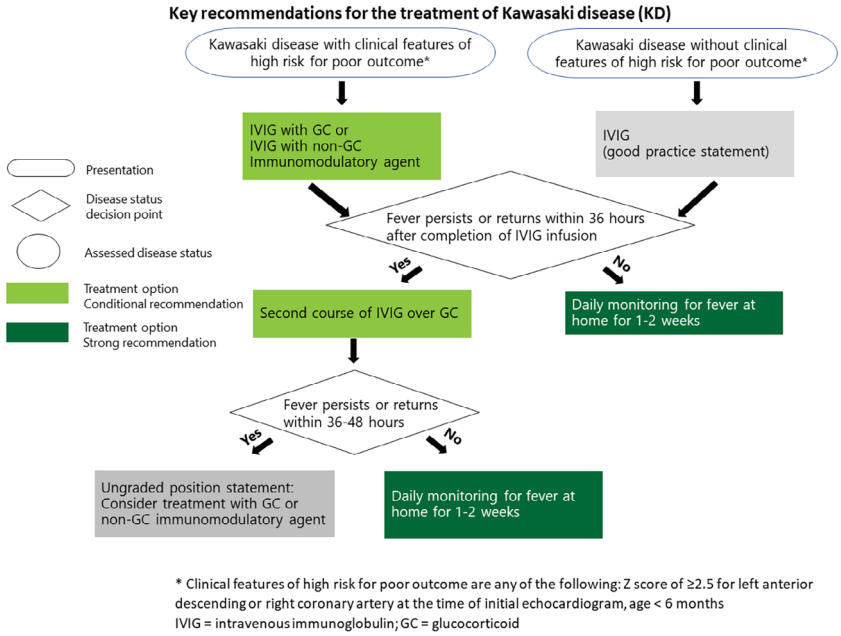
	KD PICO question informing recommendation and discussion	Level of evidence
Treatment recommendations		
Good practice statement: IVIG is the standard-of-care therapy for the initial treatment of KD.	3	High
For patients with acute KD who are at high risk of IVIG resistance or developing coronary artery aneurysms, use of IVIG with adjunctive glucocorticoids as initial therapy is **conditionally** recommended over treatment with IVIG alone.	4	Low
For patients with acute KD who are at high risk of IVIG resistance or developing coronary artery aneurysms, using IVIG with other nonglucocorticoid immunomodulatory immunosuppressive agents as initial therapy is **conditionally** recommended over treatment with IVIG alone.	5	Very low
For patients with incomplete KD, prompt treatment with IVIG at the time of diagnosis is **strongly** recommended over delaying treatment until day 10 or later.	1	Low
For patients with acute KD and suspected or diagnosed MAS, treatment with IVIG for KD and additional agents to treat MAS is **strongly** recommended.	2	Very low
For patients with acute KD and persistent fevers after initial treatment with IVIG, a second course of IVIG is **conditionally** recommended over the use of glucocorticoids.	10	Very low
Ungraded position statement: For patients with acute KD and persistent fevers after repeated treatment with IVIG, either nonglucocorticoid immunosuppressive therapy or glucocorticoids may be used.	11	Low
For patients with acute KD, using aspirin is **strongly** recommended over no aspirin.	6	Very low
For patients with acute KD with subsequent resolution of fevers, continued daily monitoring for fevers is **strongly** recommended over not monitoring for fevers.	12	Very low
For patients with acute KD who have arthritis that persists after IVIG treatment and who do not have coronary artery aneurysms, using NSAIDs to treat arthritis is **conditionally** recommended over not using NSAIDS.	13	Very low
Diagnostic imaging		
For children with suspected incomplete KD and fever, obtaining an echocardiogram with coronary artery measurements without delay is **strongly** recommended over not obtaining an echocardiogram.	D1	Very low
For children with unexplained shock physiology, obtaining an echocardiogram with coronary artery measurements is **strongly** recommended.	D2	Very low
For children with unexplained MAS, obtaining an echocardiogram with coronary artery measurements is **strongly** recommended.	D3	Very low

* For the population, intervention, comparator, and outcome (PICO) questions used in the Grading of Recommendations Assessment, Development and Evaluation methodology, as developed for Kawasaki disease (KD), please refer to Supplementary Appendix 2 (available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.42041/abstract). IVIG = intravenous immunoglobulin; MAS = macrophage activation syndrome; NSAIDs = nonsteroidal antiinflammatory drugs.

(21,23,28,29). Thus, adjunctive therapy with a nonglucocorticoid immunomodulatory agent can be considered in patients with KD who are at high risk of not responding to IVIG. For any patient considered to have features of high-risk disease, a rheumatologist or other clinician with expertise in KD should be consulted before adding an adjunctive agent (glucocorticoids or nonglucocorticoid immunomodulatory agents) to ensure correct diagnosis and appropriate utilization of adjunctive therapies. The Voting Panel also advocated for a stepwise therapeutic algorithm, in which either a glucocorticoid or nonglucocorticoid immunosuppressive agent along with IVIG is initially prescribed in high-risk patients. Currently, there is more evidence supporting the use of glucocorticoids than nonglucocorticoid immunosuppressive agents in this patient population, and further study is warranted to compare the efficacy of glucocorticoid therapy to nonglucocorticoid therapy in this population. There may be specific situations in which glucocorticoids are contraindicated, but the patient exhibits high-risk features that would indicate the need for adjunctive nonglucocorticoid immunomodulatory therapy. Once again, use of IVIG alone is appropriate if the treating physician is unsure whether a patient has high-risk features, as described in the previous recommendation, or if using a nonglucocorticoid immunomodulatory agent presents a greater risk of an adverse effect to the patient.

Recommendation: For patients with incomplete KD, prompt treatment with IVIG at the time of diagnosis is strongly recommended over delaying treatment until day 10 or later.

Incomplete KD is defined as a condition of suspected KD that lacks the sufficient number of features to meet criteria for KD (3,30) (Table 1). Patients with incomplete KD should be evaluated using the algorithm for incomplete KD as outlined in the AHA guidelines for KD (3,30). The performance of this algorithm for identifying patients with incomplete KD has been validated (30). The practice of completing diagnostic testing and initiating treatment



Key recommendations for the treatment of Kawasaki disease (KD)
Kawasaki disease with clinical features of high risk for poor outcome*
Kawasaki disease without clinical features of high risk for poor outcome*
IVIG with GC or IVIG with non-GC Immunomodulatory agent
IVIG (good practice statement)
Presentation
Disease status decision point
Assessed disease status
Treatment option Conditional recommendation
Treatment option Strong recommendation
Fever persists or returns within 36 hours after completion of IVIG infusion

No
Second course of IVIG over GC
Daily monitoring for fever at home for 1-2 weeks
Fever persists or returns within 36-48 hours
Yes
No
Ungraded position statement: Consider treatment with GC or non-GC immunomodulatory agent
Daily monitoring for fever at home for 1-2 weeks
* Clinical features of high risk for poor outcome are any of the following: Z score of ≥2.5 for left anterior descending or right coronary artery at the time of initial echocardiogram, age < 6 months
IVIG = intravenous immunoglobulin; GC = glucocorticoid

Figure 1. Key recommendations for the treatment of Kawasaki disease in patients with and those without clinical features indicating a high risk for poor outcome.

by day 10 of fever is not based on mechanisms or studies of disease pathogenesis or treatment outcomes. Instead, this "treatment deadline" was chosen as a research end point in the original studies in KD (31). It is recognized that prompt treatment prevents adverse outcomes, and patients should receive treatment as soon as the diagnosis of incomplete KD is made, rather than waiting until day 10 to see if they meet criteria for complete KD. Although delayed IVIG treatment after 10 days of fever is associated with worse outcomes (32), IVIG treatment should still be administered to patients even if they present after >10 days of fever. Thus, patients who meet the criteria for incomplete KD according to the AHA guidelines should be treated promptly to avoid adverse consequences, since the risk of developing coronary artery dilatation increases each day without treatment. This is a strong recommendation because this intervention is standard of care, and the consequence of delaying treatment may lead to significant coronary artery aneurysms or rupture, which are severe adverse outcomes. In addition, resolution of fever prior to day 10 is not an indication to withhold treatment in patients meeting criteria for incomplete or complete KD. In patients with characteristically elevated levels of acute-phase reactants, treatment is recommended, as these patients remain at high risk of developing adverse outcomes (3,33).

Recommendation: For patients with acute KD and suspected or diagnosed macrophage activation syndrome (MAS), treatment with IVIG for KD and additional agents to treat MAS is strongly recommended.

MAS, a form of secondary hemophagocytic lymphohistiocytosis (HLH), is a potentially underrecognized complication of KD (34,35). Formal diagnostic criteria for MAS in the setting of KD have not been developed. However, drawing on experience with other secondary HLH presentations, MAS may be suspected in KD patients with persistent fever, splenomegaly, elevated ferritin levels, and thrombocytopenia (35). Inadequate treatment of either KD or MAS could result in severe consequences. These include large coronary aneurysms or coronary artery stenosis, leading to death via cardiac infarct or coronary rupture in KD, or death due to multiorgan dysfunction in MAS (36).

Thus, to ensure appropriate therapy, each disease entity should be considered separately with appropriate targeted therapy. KD should be treated with IVIG as the first-line therapy, and MAS should also be treated with appropriate agents for targeting cytokine storm or underlying triggers. Anakinra and glucocorticoids are preferred for treatment in these patients over a primary HLH–directed treatment protocol with cytotoxic agents. Although no head-to-head comparison trials have been published, primary HLH–directed therapy, which has considerably more associated toxicity, may not be warranted in patients without an underlying genetic predisposition to HLH. This is a strong recommendation because the consequence of not appropriately treating KD or MAS may be associated with increased mortality.

Recommendation: For patients with acute KD and persistent fevers after initial treatment with IVIG, a second course of IVIG is conditionally recommended over the use of glucocorticoids.

Findings from 6 studies provide indirect evidence for this recommendation, though no direct comparative studies were available (37–42). For KD patients with persistent fevers after

the initial course of IVIG, studies suggest that there is no difference in coronary artery outcomes between repeating the course of IVIG versus a single dose of pulse glucocorticoids (i.e., 30 mg/kg with a maximum of 1 gm) (43). A meta-analysis of 12 studies involving 372 patients whose disease was resistant to treatment with a single course of IVIG failed to demonstrate significant differences in coronary artery outcomes between patients treated with a second dose of IVIG versus glucocorticoids versus infliximab (44). Although current evidence does not clearly indicate the superiority of a second course of IVIG over glucocorticoids, a second course of IVIG in patients who have persistent fever for >36 hours after the first dose is conditionally recommended, as it is the current standard of care. However, as a conditional recommendation, glucocorticoids are a reasonable alternative (e.g., starting at 2 mg/kg/day and tapering over 15 days or a single dose of 20–30 mg/kg). Repeated doses of IVIG may put patients at risk of hemolytic anemia, and the results of ongoing studies may alter this recommendation in the future (45–47). In patients with risk factors for hemolytic anemia with IVIG, such as non–type O blood groups, alternative therapies, such as glucocorticoids or nonglucocorticoid immunomodulatory therapy, should be considered (45,48). Combination therapy (i.e., multiple anticytokine agents) is not recommended for routine care and generally should only be considered in patients with extremely severe disease.

Ungraded Position Statement: For patients with acute KD and persistent fevers after repeated treatment with IVIG, either nonglucocorticoid immunosuppressive therapy or glucocorticoids may be used.

In patients with KD and persistent fevers after 2 doses of IVIG, use of another agent is indicated. Findings from studies of infliximab and cyclosporine for the treatment of refractory KD suggest some potential benefit of these agents (28,29). Head-to-head comparisons between these nonglucocorticoid immunosuppressive agents and glucocorticoids have not been performed. There is no clinical evidence to suggest superiority of either glucocorticoids or nonglucocorticoid immunomodulatory agents, and the Voting Panel was evenly split as to which to recommend. Thus, the Voting Panel believes that use of either class of agents would be appropriate based on the specific clinical scenario. Combination therapy (glucocorticoid with a nonglucocorticoid immunosuppressive agent) can be considered in severe cases, such as rapidly expanding aneurysms or imminently life-threatening disease.

Recommendation: For patients with acute KD, using aspirin is strongly recommended over no aspirin.

The use of aspirin in patients with KD to reduce inflammation and prevent thrombosis through its antiplatelet effect is considered standard of care. However, the optimal dosage is unclear. Historically, high dosages of aspirin (80–100 mg/kg/day) were used during the acute phase for antiinflammatory effects, but there is no evidence of benefit with high- versus low-dose aspirin (3–5 mg/kg/day) when considering coronary vascular damage (49–51). The AHA guidelines should be consulted for recommendations regarding anticoagulation in patients with larger aneurysms (3). This is a strong recommendation because aspirin is recognized to be a low-cost intervention with limited toxicity at antiplatelet dosing, and also because there are significant consequences of not inhibiting platelet activity, such as coronary artery thrombosis.

Recommendation: For patients with acute KD with subsequent resolution of fevers, continued daily monitoring is strongly recommended over not monitoring for fevers.

Patients with KD may experience recurrence of disease or treatment-refractory disease heralded by returning fever and other symptoms. In addition, the duration of fever is a predictor of coronary artery aneurysms (52). Thus, patients should be monitored daily for fevers for 1–2 weeks after discharge, with fever defined as an oral temperature in older children and a rectal temperature in infants of >38.0°C or an axillary temperature of >37.5°C. Parents or guardians should be instructed by the discharging physician on how to take a temperature and told to contact the physician should fever recur. Daily fever monitoring is strongly recommended because it is low cost, without harms, and may identify recurring KD.

Recommendation: For patients with acute KD who have arthritis that persists after IVIG treatment and who do not have coronary artery aneurysms, using nonsteroidal antiinflammatory drugs (NSAIDs) to treat arthritis is conditionally recommended over not using NSAIDS.

Patients with acute and subacute KD can develop arthritis, but treatment with IVIG decreases the incidence of arthritis in this setting from 30% to ~2–12% (53). Arthritis in KD is usually short-lived, lasting between 7 and 21 days (53–55). In general, arthritis can be treated with NSAIDs, but NSAIDs directly inhibit the ability of aspirin to acetylate cyclooxygenase 1, thus decreasing aspirin's protective effects (56). The impact of NSAID use can be partially mitigated by administering aspirin prior to NSAIDs, but combination therapy is usually not recommended given the potential increased toxicity (56).

Patients without coronary artery aneurysms generally do not require long-term treatment with aspirin. The optimal duration of treatment with aspirin in these patients is not well defined but in practice is generally 6–8 weeks. Patients with coronary artery aneurysms require long-term and potentially indefinite aspirin use (3). For patients *without* coronary artery aneurysms who do not require long-term use of aspirin and who have arthritis requiring additional therapy, aspirin can be temporarily suspended and a short course (3–4 weeks) of NSAIDs can be used as needed.

Conversely, if indefinite or long-term aspirin use is needed due to coronary artery aneurysms, then either acetaminophen, a short course of glucocorticoids, or nonsystemic NSAID pain management options (e.g., a topical NSAID) can be used. A pediatric hematologist or cardiologist should be consulted to consider an alternative anticoagulant (e.g., clopidogrel) if prolonged use of systemic NSAIDs is required (i.e., >3 weeks), especially in a patient with coronary artery aneurysms.

Diagnostic imaging

Recommendation: For children with suspected incomplete KD and fever, obtaining an echocardiogram with coronary artery measurements without delay is strongly recommended over not obtaining an echocardiogram.

Patients with incomplete KD have at least the same or an increased risk of coronary artery lesions compared to patients with classic KD (57). Therefore, in patients in whom incomplete KD is suspected, a diagnosis should be confirmed as soon as possible so that features associated with high risk of coronary artery aneurysms can be assessed, treatment can be initiated without delay, and adverse outcomes can be prevented. Echocardiographic assessment of the absolute dimensions of the coronary artery and body surface area–adjusted Z scores can help establish a diagnosis of incomplete KD and should be obtained promptly when this diagnosis is suspected. The AHA guidelines for KD management provide an algorithm for the evaluation and treatment of suspected incomplete KD (3), which has been validated (30). Echocardiography is strongly recommended in this scenario because it has minimal potential harms and may prevent adverse outcomes by prompting the treatment of incomplete KD.

Recommendation: For children with unexplained shock physiology, obtaining an echocardiogram with coronary artery measurements is strongly recommended.

Unexplained shock can be due to Kawasaki shock syndrome, a recognized manifestation of KD (58). Echocardiograms are often obtained in children with unexplained shock, especially in those with the prodrome of prolonged fever, to evaluate cardiac function and help identify the potential etiology. We recommend that the coronary arteries be included in the echocardiographic examination to evaluate for KD as a potential etiology of shock. This is strongly recommended because echocardiography has minimal potential harms and may prevent catastrophic outcomes by facilitating the diagnosis and prompt treatment of KD.

Recommendation: For children with unexplained MAS, obtaining an echocardiogram with coronary artery measurements is strongly recommended.

As noted above, KD is one of the clinical inflammatory entities that can predispose patients to the development of MAS (59). For patients with unexplained MAS, KD should be considered as a potential underlying etiology. Echocardiography with inclusion of the coronary arteries is one method of identifying KD as a potential treatable underlying condition. This is strongly recommended because echocardiography has minimal potential harms and may prevent adverse outcomes by facilitating the diagnosis and prompt treatment of KD.

DISCUSSION

This is the first guideline issued by the ACR in conjunction with the Vasculitis Foundation for the management of KD. These recommendations constitute a guide to help physicians treat KD. This guideline should not be used by any agency to restrict access to therapy or require that certain therapies must be utilized prior to other therapies.

Patients with KD in the US are often diagnosed and treated by physicians with expertise in areas other than rheumatology (e.g., pediatric cardiologists, hospitalists, or infectious disease specialists). The recommendations in this guideline focus on situations in which rheumatologists are often consulted, such as in the management of severe disease, treatment-refractory disease, arthritis, and MAS with KD. However, these recommendations are relevant to physicians treating KD regardless of their area of expertise.

The AHA has presented recommendations for the initial treatment and long-term management of KD (3). Recommendations presented in this guideline are intended to supplement the AHA guidelines and serve as an additional reference for rheumatologists who may be less familiar with KD. Emerging evidence suggesting that adjunctive therapy decreases the incidence of severe coronary artery aneurysms and accelerates regression of these aneurysms provides the basis for the recommendations concerning "high-risk" KD (23). Although aneurysms that have regressed are affected by endothelial dysfunction and therefore remain abnormal vasculature, normalized vessel caliber decreases the risk of morbidity from vessel thrombosis (3).

Finally, during the COVID-19 pandemic, a novel multisystem inflammatory syndrome in children (MIS-C) associated with SARS–CoV-2 infection emerged, with some features suggestive of KD (60,61). While as many as 50% of these patients could meet criteria for KD, many patients exhibit manifestations that are unusual for KD, including colitis, myocarditis, and neurologic changes, and often present with or develop shock (62). Further study is needed to understand the relationship between MIS-C and KD, especially Kawasaki shock syndrome. Based on clinical experience, recognition and differentiation of these patients from patients with classic KD is important. Patients who fulfill criteria for KD should be treated using the therapies discussed in this guideline. Additional research is needed to

determine optimal treatment for MIS-C with and without KD features.

In summary, the ACR and Vasculitis Foundation present these recommendations to assist physicians in managing KD. This guideline can serve as a resource for basic principles of management and will evolve as new treatment strategies for this disease are identified.

ACKNOWLEDGMENTS

We thank Anne M. Ferris, MBBS, Ora Gewurz-Singer, MD, Rula Hajj-Ali, MD, Eric Matteson, MD, MPH, Robert F. Spiera, MD, Linda Wagner-Weiner, MD, MS, and Kenneth J. Warrington, MD, for serving on the Expert Panel. We thank Antoine G. Sreih, MD and Gary S. Hoffman, MD, MS, for their contributions during the early phases of this project as members of the Core Team. Dr. Hoffman's participation ended July 2018 due to personal reasons. Dr. Sreih's involvement ended in December 2018 when he became primarily employed by industry, which precluded his continued participation in this project. We thank Joyce Kullman (Vasculitis Foundation) for her assistance with recruitment for the Patient Panel. We thank the patients who (along with authors Kathy A. Full and Omar I. Vitobaldi) participated in the Patient Panel meeting: Jane Ascroft, Scott A. Brunton, Dedra DeMarco, Thomas Fitzpatrick, Jenn Gordon, Maria S. Mckay, Sandra Nye, Stephanie Sakson, and Ben Wilson. We thank Robin Arnold, Catherine E. Najem, MD, MSCE, and Amit Aakash Shah, MD, MPH, for their assistance with the literature review. We thank the ACR staff, including Ms. Regina Parker, for assistance in organizing the face-to-face meeting and coordinating the administrative aspects of the project, and Ms. Cindy Force for assistance in manuscript preparation. We thank Ms. Janet Waters for help in developing the literature search strategy and performing the initial literature search, and Ms. Janet Joyce for performing the update searches.

AUTHOR CONTRIBUTIONS

All authors were involved in drafting the article or revising it critically for important intellectual content, and all authors approved the final version to be published. Dr. Chung had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Study conception and design. Gorelik, Chung, Friedman, Sule, Yildirim-Toruner, Langford, Maz, Abril, Guyatt, Full, Stone, Sundel, Vitobaldi, Husainat, Turgunbaev, Turner, Mustafa.

Acquisition of data. Gorelik, Chung, Binstadt, Lapidus, Kim, Sule, Yildirim-Toruner, Full, Grayson, Stone, Sundel, Byram, Dua, Husainat, James, Kalot, Lin, Springer, Turgunbaev, Villa-Forte, Mustafa.

Analysis and interpretation of data. Gorelik, Chung, Ardalan, Binstadt, Hayward, Imundo, Lapidus, Kim, Son, Sule, Tremoulet, Van Mater, Yildirim-Toruner, Abril, Archer, Conn, Full, Grayson, Ibarra, Merkel, Rhee, Seo, Stone, Sundel, Warner, Byram, Dua, Husainat, Kalot, Lin, Springer, Turgunbaev, Villa-Forte, Mustafa.

2022 American College of Rheumatology/European Alliance of Associations for Rheumatology Classification Criteria for Microscopic Polyangiitis

Ravi Suppiah,[1] Joanna C. Robson,[2] Peter C. Grayson,[3] Cristina Ponte,[4] Anthea Craven,[5] Sara Khalid,[5] Andrew Judge,[6] Andrew Hutchings,[7] Peter A. Merkel,[8] Raashid A. Luqmani,[5] and Richard A. Watts[9]

This criteria set has been approved by the American College of Rheumatology (ACR) Board of Directors and the European Alliance of Associations for Rheumatology (EULAR) Executive Committee. This signifies that the criteria set has been quantitatively validated using patient data, and it has undergone validation based on an independent data set. All ACR/EULAR-approved criteria sets are expected to undergo intermittent updates.

The ACR is an independent, professional, medical and scientific society that does not guarantee, warrant, or endorse any commercial product or service.

Objective. To develop and validate classification criteria for microscopic polyangiitis (MPA).

Methods. Patients with vasculitis or comparator diseases were recruited into an international cohort. The study proceeded in 5 phases: 1) identification of candidate items using consensus methodology, 2) prospective collection of candidate items present at the time of diagnosis, 3) data-driven reduction of the number of candidate items, 4) expert panel review of cases to define the reference diagnosis, and 5) derivation of a points-based risk score for disease classification in a development set using least absolute shrinkage and selection operator logistic regression, with subsequent validation of performance characteristics in an independent set of cases and comparators.

Results. The development set for MPA consisted of 149 cases of MPA and 408 comparators. The validation set consisted of an additional 142 cases of MPA and 414 comparators. From 91 candidate items, regression analysis identified 10 items for MPA, 6 of which were retained. The final criteria and their weights were as follows: perinuclear antineutrophil cytoplasmic antibody (ANCA) or anti–myeloperoxidase-ANCA positivity (+6), pauci-immune glomerulonephritis (+3), lung fibrosis or interstitial lung disease (+3), sino-nasal symptoms or signs (−3), cytoplasmic ANCA or anti–proteinase 3 ANCA positivity (−1), and eosinophil count ≥1 × 10^9/liter (−4). After excluding mimics of vasculitis, a patient with a diagnosis of small- or medium-vessel vasculitis could be classified as having MPA with a cumulative score of ≥5 points. When these criteria were tested in the validation data set, the sensitivity was 91% (95% confidence interval [95% CI] 85–95%) and the specificity was 94% (95% CI 92–96%).

Conclusion. The 2022 American College of Rheumatology/European Alliance of Associations for Rheumatology classification criteria for MPA are now validated for use in clinical research.

This article is published simultaneously in the March 2022 issue of *Annals of the Rheumatic Diseases*.

The Diagnostic and Classification Criteria in Vasculitis (DCVAS) study, of which the development of these classification criteria was a part, was funded by grants from the American College of Rheumatology (ACR), the European Alliance of Associations for Rheumatology (EULAR), the Vasculitis Foundation, and the University of Pennsylvania Vasculitis Center.

INTRODUCTION

The first description of "periarteritis nodosa" was made by Kussmaul and Maier in 1866 (1). In 1948, Davson et al described 14 cases at autopsy that fitted the clinical description of periarteritis nodosa (2). They divided the cases into 2 groups based on the histologic findings in the kidneys. The clinical presentations of both groups were similar, but their pathologic features differed: 9 patients showed a distinctive pattern of necrotizing glomerulonephritis with no arterial aneurysms, whereas the other 5 patients showed no glomerular lesions in the kidney but had widespread renal arterial aneurysms and renal infarcts. This is the first time that a clear distinction was made between the microscopic form of polyarteritis nodosa (now called microscopic polyangiitis [MPA]) and classic polyarteritis nodosa (PAN). The 1990 American College of Rheumatology (ACR) criteria for the classification of vasculitis did not make this distinction; instead both entities were included under the term "polyarteritis nodosa" (3) or possibly "granulomatosis with polyangiitis" (then called Wegener's granulomatosis).

The publication that resulted from the 1994 Chapel Hill Consensus Conference (CHCC) aimed to standardize the nomenclature and commented that "different names are being used for the same disease and the same name is being used for different diseases" (4). The distinction between MPA and PAN is recognized in the CHCC definitions. The main discriminating feature between MPA and PAN is the presence in MPA of pauci-immune vasculitis in arterioles, venules, or capillaries. PAN is restricted to a medium-vessel disease, and MPA is a predominantly small-vessel vasculitis that can also involve medium-sized vessels.

The resulting inconsistency between disease definitions and existing classification criteria highlights an important need to update the classification criteria and to include MPA as its own entity. Additionally, over time there have been improvements in our understanding of the different forms of vasculitis, which have been informed in part by routine testing for antineutrophil cytoplasmic antibody (ANCA) in patients with vasculitis and increased utilization of cross-sectional imaging, both of which have occurred since the 1990 ACR criteria were published. Indeed, most investigators regard MPA as part of the group of small-vessel vasculitides related to the presence of ANCA. This article outlines the development and validation of the new ACR/European Alliance of Associations for Rheumatology (EULAR)–endorsed classification criteria for MPA.

METHODS

A detailed and complete description of the methods involved in the development and validation of the classification criteria for MPA is provided in Supplementary Appendix 1, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41983/abstract. Briefly, an international Steering Committee comprising clinician investigators with expertise in vasculitis, statisticians, and data managers was established to oversee the overall Diagnostic and Classification Criteria in Vasculitis (DCVAS) project. The Steering Committee established a 5-stage plan using data-driven and consensus methodology to develop the criteria for each of 6 forms of vasculitis.

Stage 1: generation of candidate classification items for the systemic vasculitides. Candidate classification items were generated by expert opinion and reviewed by a group of vasculitis experts across a range of specialties using a nominal group technique.

Stage 2: DCVAS prospective observational study. A prospective, international multisite observational study was conducted (see Appendix A for study investigators and sites). Ethical approval was obtained from national and local ethics committees. Consecutive patients representing the full spectrum of disease were recruited from academic and community practices. Patients were included if they were 18 years or older and had a diagnosis of vasculitis or a condition that mimics vasculitis. Patients with ANCA-associated vasculitis (AAV) could only be enrolled within 2 years of diagnosis. Only data present at diagnosis were recorded.

Stage 3: refinement of candidate items specifically for AAV. The Steering Committee conducted a data-driven process to reduce the number of candidate items of relevance to cases and comparators for AAV. Items were selected for exclusion if they had a prevalence of <5% within the data set and/or they were not clinically relevant for classification criteria (e.g., related to infection, malignancy, or demographic characteristics). Low-frequency items of clinical importance could be combined, when appropriate.

Stage 4: expert review to derive a gold standard–defined set of cases of AAV. Experts in vasculitis from a wide range of geographic locations and specialties reviewed all submitted cases of vasculitis and a random selection of mimics of

Submitted for publication February 28, 2020; accepted in revised form September 21, 2021.

vasculitis. Each reviewer was asked to review ~50 submitted cases to confirm the diagnosis and to specify the certainty of their diagnosis as follows: very certain, moderately certain, uncertain, or very uncertain. Only cases agreed upon with at least moderate certainty were retained for further analysis.

Stage 5: derivation and validation of the final classification criteria for MPA. The DCVAS AAV data set was randomly split into development (50%) and validation (50%) sets. Comparisons were performed between cases of MPA and a comparator group randomly selected from the DCVAS cohort in the following proportions: another type of AAV (including granulomatosis with polyangiitis [GPA] and eosinophilic granulomatosis with polyangiitis [EGPA]), 60%; another form of small-vessel vasculitis (e.g., cryoglobulinemic vasculitis) or medium-vessel vasculitis (e.g., PAN), 40%. Least absolute shrinkage and selection operator (lasso) logistic regression was used to identify items from the data set and create a parsimonious model including only the most important items. The final items in the model were formulated into a clinical risk-scoring tool with each factor assigned a weight based on its respective regression coefficient. A threshold that best balanced sensitivity and specificity was identified for classification.

In sensitivity analyses, the final classification criteria were applied to an unselected population of cases and comparators from the DCVAS data set based on the submitting physician diagnosis.

RESULTS

Generation of candidate classification items for the systemic vasculitides. The Steering Committee identified >1,000 candidate items for the DCVAS case report form (see Supplementary Appendix 2, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41983/abstract).

DCVAS prospective observational study. Between January 2011 and December 2017, the DCVAS study recruited 6,991 participants from 136 sites in 32 countries. Information on the DCVAS sites, investigators, and participants is listed in Supplementary Appendices 3, 4, and 5, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41983/abstract.

Refinement of candidate items specifically for AAV. Following a data-driven and expert consensus process, 91 items from the DCVAS case report form were retained for regression analysis, including 45 clinical (14 composite), 18 laboratory (2 composite), 12 imaging (all composite), and 16 biopsy (1 composite) items. Some clinical items were removed in favor of similar but more specific pathophysiologic descriptors. For example, "Hearing loss or reduction" was removed, and the composite item "Conductive hearing loss/sensorineural hearing loss" was retained. See Supplementary Appendix 6, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41983/abstract, for the final candidate items used in the derivation of the classification criteria for GPA, MPA, and EGPA.

Expert review to derive a gold standard–defined final set of cases of AAV. Fifty-five independent experts reviewed vignettes derived from the case report forms for 2,871 cases submitted with a diagnosis of either small-vessel vasculitis (90% of case report forms) or another type of vasculitis or a mimic of vasculitis (10% of case report forms). The characteristics of the expert reviewers are shown in Supplementary Appendix 7, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41983/abstract. A flow chart showing the results of the expert review process is shown in Supplementary Appendix 8, available on the *Arthritis &*

Table 1. Demographic and disease features of cases of MPA and comparators*

	MPA (n = 291)	Comparators (n = 822)†	*P*
Age, mean ± SD years	65.5 ± 13.2	52.0 ± 16.9	<0.001
Sex, no. (%) female	164 (56.4)	394 (47.9)	0.016
Maximum serum creatinine, mean			<0.001
μmoles/liter	126.4	185.2	
mg/dl	1.4	2.1	
cANCA positive, no. (%)	11 (3.8)	257 (31.3)	<0.001
pANCA positive, no. (%)	236 (81.1)	136 (16.5)	<0.001
Anti–PR3-ANCA positive, no. (%)	6 (2.1)	265 (32.2)	<0.001
Anti–MPO-ANCA positive, no. (%)	279 (95.9)	142 (17.3)	<0.001
Maximum eosinophil count ≥1 × 10^9/liter, no. (%)	15 (5.2)	244 (29.7)	<0.001

* cANCA = cytoplasmic antineutrophil cytoplasmic antibody; pANCA = perinuclear ANCA; anti–PR3-ANCA = anti–proteinase 3–ANCA; anti–MPO-ANCA = anti–myeloperoxidase-ANCA.
† Diagnoses of comparators for the classification criteria for microscopic polyangiitis (MPA) included granulomatosis with polyangiitis (n = 300), eosinophilic granulomatosis with polyangiitis (n = 226), polyarteritis nodosa (n = 51), non–ANCA-associated small-vessel vasculitis that could not be subtyped (n = 51), Behçet's disease (n = 50), IgA vasculitis (n = 50), cryoglobulinemic vasculitis (n = 34), ANCA-associated vasculitis that could not be subtyped (n = 25), primary central nervous system vasculitis (n = 19), and anti–glomerular basement membrane disease (n = 16).

Rheumatology website at http://onlinelibrary.wiley.com/doi/10.1002/art.41983/abstract. A total of 2,072 cases (72%) passed the process and were designated as cases of vasculitis; these cases were used for the stage 5 analyses.

After expert panel review by 55 investigators, 269 of 404 of the cases retained the submitting physician diagnosis of MPA, and 22 additional cases were reclassified as having MPA by consensus of 2 expert reviewers. Compared to the 291 patients with a reference diagnosis of MPA, the 135 cases that were excluded had lower rates of perinuclear ANCA (pANCA) or anti–myeloperoxidase-ANCA (anti–MPO-ANCA) positivity (76% versus 98%; $P < 0.01$), were less likely to have pauci-immune glomerulonephritis (16% versus 49%; $P < 0.01$), were more likely to have maximum eosinophil counts $\geq 1 \times 10^9$/liter (12% versus 6%; $P = 0.02$), and were more likely to be cytoplasmic ANCA– or proteinase 3–ANCA–positive (20% versus 4%; $P < 0.01$). There were 822 comparators randomly selected for analysis. Table 1 shows the demographic and disease features of the 1,113 cases included in this analysis (291 patients with MPA and 822 comparators), of which 557 (50%; 149 patients with MPA and 408 comparators) were in the development set, and 556 (50%; 142 patients with MPA and 414 comparators) were in the validation set.

Derivation and validation of the final classification criteria for MPA. Lasso regression of the previously selected 91 items yielded 10 independent items for MPA (see Supplementary Appendix 9C, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41983/abstract). Each item was then adjudicated by the DCVAS Steering Committee for inclusion based on clinical relevance and specificity to MPA, resulting in 6 final items. Weighting of an individual criterion was based on logistic regression fitted to the 6 selected items (see Supplementary Appendix 10C, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41983/abstract).

2022 AMERICAN COLLEGE OF RHEUMATOLOGY / EUROPEAN ALLIANCE OF ASSOCIATIONS FOR RHEUMATOLOGY

CLASSIFICATION CRITERIA FOR **MICROSCOPIC POLYANGIITIS**

CONSIDERATIONS WHEN APPLYING THESE CRITERIA

- **These classification criteria should be applied to classify a patient as having microscopic polyangiitis when a diagnosis of small- or medium-vessel vasculitis has been made**
- **Alternate diagnoses mimicking vasculitis should be excluded prior to applying the criteria**

CLINICAL CRITERIA

Nasal involvement: bloody discharge, ulcers, crusting, congestion, blockage or septal defect / perforation	-3

LABORATORY, IMAGING, AND BIOPSY CRITERIA

Positive test for perinuclear antineutrophil cytoplasmic antibodies (pANCA) or antimyeloperoxidase (anti-MPO) antibodies ANCA positive	+6
Fibrosis or interstitial lung disease on chest imaging	+3
Pauci-immune glomerulonephritis on biopsy	+3
Positive test for cytoplasmic antineutrophil cytoplasmic antibodies (cANCA) or antiproteinase 3 (anti-PR3) antibodies	-1
Blood eosinophil count ≥ 1 x10^9/liter	-4

Sum the scores for 6 items, if present. A score of ≥ 5 is needed for classification of MICROSCOPIC POLYANGIITIS.

Figure 1. 2022 American College of Rheumatology/European Alliance of Associations for Rheumatology classification criteria for microscopic polyangiitis.

Model performance. Use of a cutoff of ≥5 in total risk score (see Supplementary Appendix 11C, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41983/abstract, for different cut points) yielded a sensitivity of 90.8% (95% confidence interval [95% CI] 84.9–95.0%) and a specificity of 94.2% (95% CI 91.5–96.3%) in the validation set. The area under the curve for the model was 0.98 (95% CI 0.97–0.99) in the development set and 0.97 (95% CI 0.95–0.98) in the validation set for the final MPA classification criteria (Supplementary Appendix 12C, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41983/abstract). The final classification criteria for MPA are shown in Figure 1 (for the slide presentation version, see Supplementary Figure 1, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41983/abstract).

Sensitivity analysis. The classification criteria for MPA were applied to 2,871 patients in the DCVAS database using the original physician-submitted diagnosis (n = 404 cases of MPA and 2,467 randomly selected comparators). Use of the same cut point of ≥5 points for the classification for MPA yielded a similar specificity of 92.5% but a lower sensitivity of 82.4%. This is consistent with the a priori hypothesis that specificity would remain unchanged but sensitivity would be reduced in a population with fewer clearcut diagnoses of MPA (i.e., cases that did not pass expert panel review).

DISCUSSION

Presented here are the 2022 ACR/EULAR MPA classification criteria. These are the first formal criteria for MPA. A 5-stage approach has been used, underpinned by data from the multinational prospective DCVAS study and informed by expert review and consensus at each stage. The comparator group for developing and validating the criteria were predominantly patients with other forms of AAV and other small- and medium-vessel vasculitides, the clinical entities where discrimination from MPA is difficult, but important. The new criteria for MPA have excellent sensitivity and specificity and incorporate ANCA testing and modern imaging techniques. The criteria were designed to have face and content validity for use in clinical trials and other research studies.

These criteria are validated and intended for the purpose of *classification* of vasculitis and are not appropriate for use in establishing a *diagnosis* of vasculitis. The aim of the classification criteria is to differentiate cases of MPA from similar types of vasculitis in research settings. Therefore, the criteria should only be applied when a diagnosis of small- or medium-vessel vasculitis has been made and all potential "vasculitis mimics" have been excluded. The exclusion of mimics is a key aspect of many classification criteria, including those for Sjögren's syndrome (5) and rheumatoid arthritis (6). The 1990 ACR classification criteria for vasculitis perform poorly when used for diagnosis (i.e., when used to differentiate between cases of vasculitis versus mimics without vasculitis) (7), and it is expected that the 2022 criteria would also perform poorly if used inappropriately as diagnostic criteria in people in whom alternative diagnoses, such as infection or other non-vasculitis inflammatory diseases, are still being considered. The relatively low weight assigned to glomerulonephritis in these classification criteria highlights the distinction between classification and diagnostic criteria. While detection of kidney disease is important to diagnose MPA, glomerulonephritis is common among patients with either GPA or MPA and thus does not function as a strong classifier between these conditions.

MPA was not recognized as a separate entity in the 1990 ACR classification criteria for vasculitis, although the disease was recognized as pathologically distinct from PAN over 40 years earlier. This omission of MPA caused difficulties in defining clear homogeneous populations for research; thus, over the last 2 decades, investigators have often relied on the disease definitions of the CHCC nomenclature for eligibility criteria when enrolling patients with MPA into clinical trials (4,8–11). This approach resulted in heterogeneity between patients enrolled in therapeutic trials and epidemiologic studies (12). Due to inconsistent methods employed by researchers when applying the 1990 ACR criteria and the CHCC definitions in parallel, the European Medicines Agency (EMA) convened meetings to develop a consensus on how to utilize the 2 systems, leading to the publication of the EMA algorithm in 2007 (13). The algorithm works by first excluding EGPA and GPA, and then relying on the CHCC histologic descriptions to discriminate between MPA and PAN. The new 2022 ACR/EULAR classification criteria for MPA and other vasculitides provide validated criteria that can replace the EMA interim solution and should harmonize future research studies.

A potential limitation of these new criteria is that, through the expert panel consensus methodology, only the most definite cases were included in the analyses. However, the purpose of these criteria is to enable homogeneous groupings so that individual diseases can be studied. Overall, the use of more definitive cases is consistent with the purpose of classification criteria. Additionally, positive testing for MPO-ANCA is weighted heavily in the criteria, and it is theoretically possible to classify a patient as having MPA on the basis of a positive test for MPO-ANCA only. However, the criteria are intended to only be applied to patients with an established diagnosis of small- or medium-vessel vasculitis; in this setting, the criteria sets should result in a reduction of the score away from a classification of MPA if the patient has features of another form of AAV. When criteria were tested in a much less clearly defined population using the submitting physician diagnosis as the gold standard, the sensitivity of the criteria fell substantially despite 91% of this group being pANCA- or MPO-ANCA positive, which supports the contention that ANCA positivity is not overly dominant for the classification. Nonetheless, ANCA testing is obviously a key discriminator between the different forms of AAV and other small- and medium-vessel vasculitides.

There are some additional study limitations to consider. Although this was the largest international study ever conducted in vasculitis, most patients were recruited from Europe, Asia, and North America. The performance characteristics of the criteria should be further tested in African and South American populations, which may have different clinical presentations of vasculitis. These criteria were developed using data collected from adult patients with vasculitis. Although the clinical characteristics of MPA and the other vasculitides which these criteria were tested against are not known to differ substantially between adults and children, these criteria should be applied to children with some caution. The scope of the criteria is intentionally narrow and applies only to patients who have been diagnosed as having vasculitis. Diagnostic criteria are not specified. The criteria are intended to identify homogeneous populations of disease and, therefore, may not be appropriate for studies focused on the full spectrum of clinical heterogeneity in these conditions. To maximize relevance and face validity of the new criteria, study sites and expert reviewers were recruited from a broad range of countries and different medical specialties. Nonetheless, the majority of patients were recruited from academic rheumatology or nephrology units, which could have introduced referral bias.

The 2022 ACR/EULAR classification criteria for MPA are the product of a rigorous methodologic process that utilized an extensive data set generated by the work of a remarkable international group of collaborators. These are the first classification criteria for this disease. The criteria can now be applied to patients who have been diagnosed as having a small- or medium-vessel vasculitis. These criteria have been endorsed by the ACR and EULAR and are now ready for use to differentiate one type of vasculitis from another to define populations in research studies.

Guidelines and recommendations developed and/or endorsed by the American College of Rheumatology (ACR) are intended to provide guidance for particular patterns of practice and not to dictate the care of a particular patient. The ACR considers adherence to the recommendations within this guideline to be voluntary, with the ultimate determination regarding their application to be made by the physician in light of each patient's individual circumstances. Guidelines and recommendations are intended to promote beneficial or desirable outcomes but cannot guarantee any specific outcome. Guidelines and recommendations developed and endorsed by the ACR are subject to periodic revision as warranted by the evolution of medical knowledge, technology, and practice. ACR recommendations are not intended to dictate payment or insurance decisions, and drug formularies or other third-party analyses that cite ACR guidelines should state this. These recommendations cannot adequately convey all uncertainties and nuances of patient care.

The American College of Rheumatology is an independent, professional, medical and scientific society that does not guarantee, warrant, or endorse any commercial product or service.

Objective. To provide evidence-based recommendations and expert guidance for the management of systemic polyarteritis nodosa (PAN).

Methods. Twenty-one clinical questions regarding diagnostic testing, treatment, and management were developed in the population, intervention, comparator, and outcome (PICO) format for systemic, non–hepatitis B–related PAN. Systematic literature reviews were conducted for each PICO question. The Grading of Recommendations Assessment, Development and Evaluation methodology was used to assess the quality of evidence and formulate recommendations. Each recommendation required ≥70% consensus among the Voting Panel.

Results. We present 16 recommendations and 1 ungraded position statement for PAN. Most recommendations were graded as conditional due to the paucity of evidence. These recommendations support early treatment of severe PAN with cyclophosphamide and glucocorticoids, limiting toxicity through minimizing long-term exposure to both treatments, and the use of imaging and tissue biopsy for disease diagnosis. These recommendations endorse minimizing risk to the patient by using established therapy at disease onset and identify new areas where adjunctive therapy may be warranted.

Conclusion. These recommendations provide guidance regarding diagnostic strategies, use of pharmacologic agents, and imaging for patients with PAN.

The article is published simultaneously in *Arthritis & Rheumatology*.

INTRODUCTION

Polyarteritis nodosa (PAN) is a systemic necrotizing vasculitis that primarily affects medium-sized vessels (1). Patients frequently present with systemic symptoms such as fever and weight loss. The most common clinical presentations include neurologic manifestations such as mononeuritis multiplex and peripheral neuropathy, cutaneous manifestations such as nodules and livedo reticularis, renal manifestations such as hypertension, and gastrointestinal manifestations such as abdominal pain (2). Diagnosis is generally confirmed by tissue biopsy of an affected organ or angiography if tissue biopsy cannot be obtained. Typical histologic findings include mixed-cell inflammatory infiltrates in the vessel wall and fibrinoid necrosis, with an absence of granulomas and giant cells (3). Findings on angiography include saccular or fusiform aneurysms and stenotic lesions in the mesenteric, hepatic, and renal arteries and their subsequent branches. Although PAN is becoming increasingly rare due to the prevention of hepatitis B viral (HBV) infection, it remains a potentially devastating diagnosis, with severe PAN having a mortality rate of 40% at 5 years (3).

Given the increasing options available to treat systemic vasculitis, the American College of Rheumatology (ACR) and the Vasculitis Foundation (VF) supported the development of guidelines for the management of large, medium, and small vessel vasculitis. This guideline presents evidence-based recommendations for the diagnostic testing, treatment, and management of PAN as an exemplar of medium vessel vasculitis. Of note, this guideline focuses on systemic PAN. Since HBV-associated PAN as well as cutaneous PAN are generally managed differently from systemic idiopathic PAN, they were excluded from this guideline.

Although this guideline may inform an international audience, these recommendations were developed considering the experience with and availability of treatment and diagnostic options in the US.

METHODS

This guideline followed the ACR guideline development process (https://www.rheumatology.org/Practice-Quality/Clinical-Support/Clinical-Practice-Guidelines) using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) methodology to rate the quality of evidence and develop recommendations (4,5). ACR policy guided the management of conflicts of interest and disclosures (https://www.rheumatology.org/Practice-Quality/Clinical-Support/Clinical-Practice-Guidelines/Vasculitis). Supplementary Appendix 1 (available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24633/abstract) presents a detailed description of the methods. Briefly, the Literature Review team undertook systematic literature reviews for predetermined questions specifying the clinical population, intervention, comparator, and outcomes (PICO). An in-person Patient Panel of 11 individuals with different types of vasculitis (1 patient with PAN) was moderated by a member of the Literature Review team (ABD). This Patient Panel reviewed the evidence report (along with a summary and interpretation by the moderator) and provided patient perspectives and preferences. An Expert Panel provided expert knowledge to inform discussion of the PICO questions and findings of the literature review. The Voting Panel comprised 9 adult rheumatologists, 5 pediatric rheumatologists, and 2 patients; they reviewed the Literature Review team's evidence summaries and, bearing in mind the Patient Panel's deliberations, formulated and voted on recommendations. A recommendation required ≥70% consensus among the Voting Panel.

How to interpret the recommendations

A *strong* recommendation is typically supported by moderate- to high-quality evidence (e.g., multiple randomized controlled

trials). For a strong recommendation, the recommended course of action would apply to all or almost all patients. Only a small proportion of clinicians/patients would not want to follow the recommendation. In rare instances, a strong recommendation may be based on very low– to low-certainty evidence. For example, an intervention may be strongly recommended if it is considered low-cost, without harms, and the consequence of not performing the intervention may be catastrophic. An intervention may be strongly recommended against if there is high certainty that the intervention leads to more harm than the comparison with very low or low certainty about its benefit (6).

A *conditional* recommendation is generally supported by lower-quality evidence or a close balance between desirable and undesirable outcomes. For a conditional recommendation, the recommended course of action would apply to the majority of the patients, but the alternative is a reasonable consideration. Conditional recommendations always warrant a shared decision-making approach. We specify conditions under which the alternative may be considered.

In some instances, the committee found that the evidence for a particular PICO question did not support a graded recommendation or did not favor one intervention over the other. However, the Voting Panel believed that the PICO question addressed a commonly encountered clinical question and thus felt that providing guidance for this question was warranted. For these situations, we present "ungraded position statements," which reflect general views of the Voting Panel.

In this evidence-based guideline, we explicitly used the best evidence available and present that in a transparent manner for the clinician reader/user (7). In some instances, this includes randomized trials in which the interventions under consideration are directly compared. The GRADE system rates evidence that comes exclusively from the collective experience of the Voting Panel and Patient Panel members as "very low quality" evidence (5).

For each recommendation, details regarding the PICO questions and the GRADE evidence tables can be found in Supplementary Appendix 2 (http://onlinelibrary.wiley.com/doi/10.1002/acr.24633/abstract).

RESULTS

For the evidence report, the Literature Review team summarized 127 articles to address 21 PICO questions for PAN.

The following recommendations and ungraded position statements are for systemic PAN and do not apply to isolated cutaneous or HBV-related PAN. Table 1 presents definitions of selected terms used in the recommendations, including the definition of severe and nonsevere disease, as well as dosing ranges for glucocorticoids. Table 2 presents the recommendations with their supporting PICO questions and levels of evidence. Figure 1 provides key recommendations for the treatment for PAN. All but 1 of the recommendations are conditional, primarily due to lack of high-quality evidence (e.g., randomized controlled trials) supporting the recommendation.

Vascular imaging, tissue biopsy, and diagnostic testing

Recommendation: For patients with suspected PAN, we conditionally recommend using abdominal vascular imaging to aid in establishing a diagnosis and determining the extent of disease.

Evidence for the use of routine diagnostic imaging is limited, with no comparative trials available. In single-arm studies that were performed when diagnostic criteria for PAN were not well defined,

Table 1. Definitions of selected terms used in the recommendations for PAN*

Term	Definition
Disease states	
Suspected disease	Clinical signs and/or symptoms suggestive of PAN and not explained by other conditions
Active disease	New, persistent, or worsening clinical signs and/or symptoms attributed to PAN and not related to prior damage
Severe disease	Vasculitis with life- or organ-threatening manifestations (e.g., renal disease, mononeuritis multiplex, muscle disease, mesenteric ischemia, coronary involvement, limb/digit ischemia)
Nonsevere disease	Vasculitis without life- or organ-threatening manifestations (e.g., mild systemic symptoms, uncomplicated cutaneous disease, mild inflammatory arthritis)
Remission	Absence of clinical signs or symptoms attributed to PAN, on or off immunosuppressive therapy
Refractory disease	Persistent active disease despite an appropriate course of immunosuppressive therapy
Relapse	Recurrence of active disease following a period of remission
Treatments	
IV pulse GCs	IV methylprednisolone 500–1,000 mg/day (adults) or 30 mg/kg/day (children; maximum 1,000 mg/day) or equivalent for 3–5 days
High-dose oral GCs	Prednisone 1 mg/kg/day (adults; generally up to 80 mg/day) or 1–2 mg/kg/day (children; generally up to 60 mg/day) or equivalent
Moderate-dose oral GCs	Prednisone 0.25–0.5 mg/kg/day (adults; generally 10–40 mg/day) or ~0.5 mg/kg/day (children; generally 10–30 mg/day) or equivalent
Low-dose oral GCs	Prednisone ≤10 mg/day (adults) or ≤0.2 mg/kg/day (children; maximum 10 mg/day) or equivalent
Non-GC immunosuppressive therapy	Azathioprine, cyclophosphamide, methotrexate, mycophenolate mofetil

* PAN = polyarteritis nodosa; IV = intravenous; GCs = glucocorticoids.

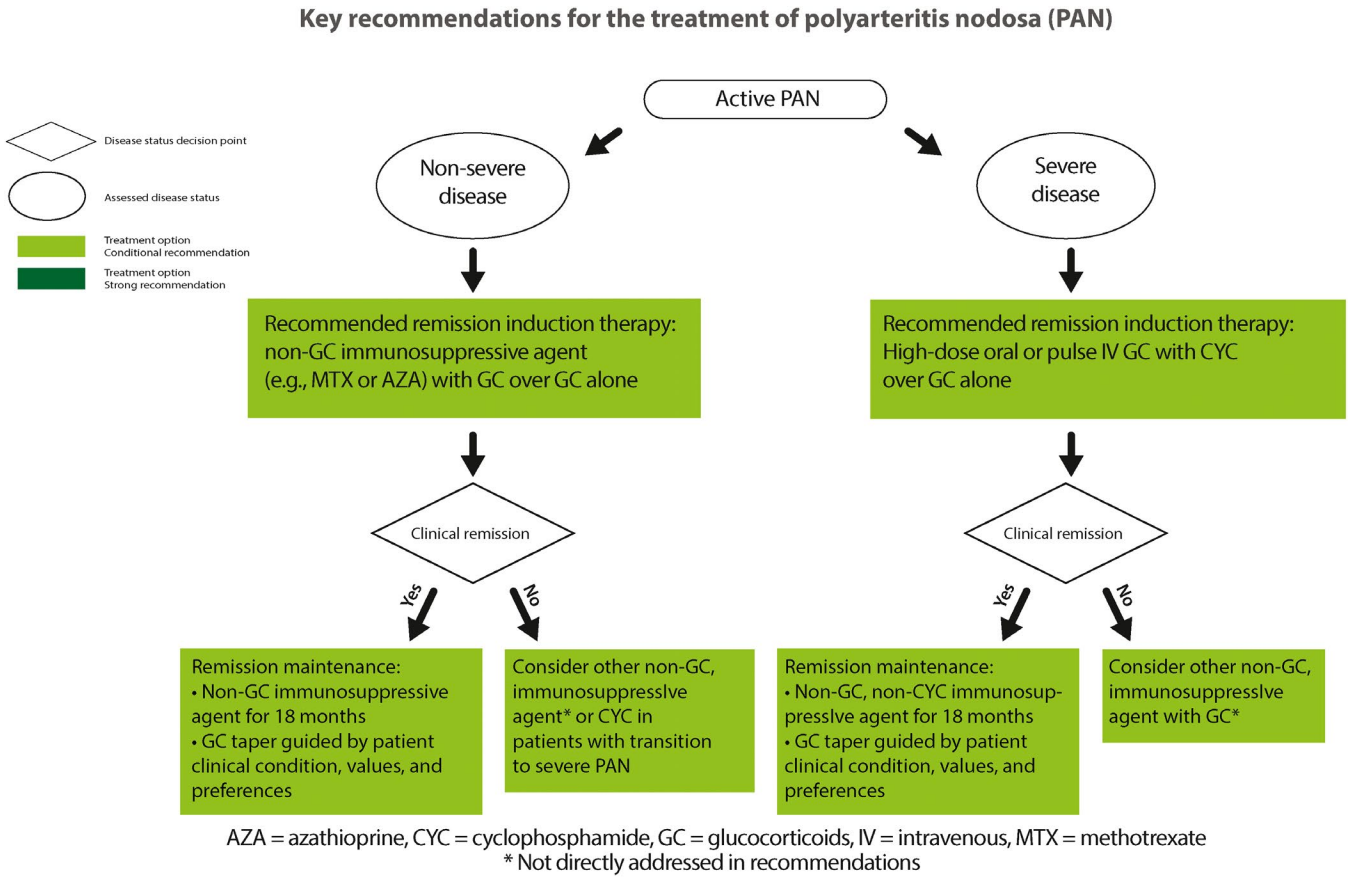
Table 2. Recommendations/statements for the management of PAN*

Recommendation/statement	PICO question informing recommendation and discussion	Level of evidence
Vascular imaging, tissue biopsy, and diagnostic testing		
Recommendation: For patients with suspected PAN, we conditionally recommend using abdominal vascular imaging to aid in establishing a diagnosis and determining the extent of disease.	1	Very low
Recommendation: For patients with a history of severe PAN with abdominal involvement who become clinically asymptomatic, we conditionally recommend follow-up abdominal vascular imaging.	19, 20	Very low
Recommendation: For patients with suspected PAN involving the skin, we conditionally recommend obtaining a deep-skin biopsy specimen (i.e., a biopsy reaching the medium-sized vessels of the dermis) over a superficial skin punch biopsy to aid in establishing a diagnosis.	2	Very low
Recommendation: For patients with suspected PAN and peripheral neuropathy (motor and/or sensory), we conditionally recommend obtaining a combined nerve and muscle biopsy over a nerve biopsy alone to aid in establishing a diagnosis.	3	Very low
Recommendation: For patients with a history of peripheral motor neuropathy secondary to PAN, we conditionally recommend serial neurologic examinations instead of repeated electromyography/nerve conduction studies (e.g., every 6 months) to monitor disease activity.	21	Very low
Treatment of active disease		
Recommendation: For patients with newly diagnosed active, severe PAN, we conditionally recommend initiating treatment with IV pulse GCs over high-dose oral GCs.	4	Very low
Recommendation: For patients with newly diagnosed active, severe PAN, we conditionally recommend initiating treatment with cyclophosphamide and high-dose GCs over high-dose GCs alone.	5, 6, 10	Very low to low
Recommendation: For patients with newly diagnosed active, severe PAN, we conditionally recommend initiating treatment with cyclophosphamide and GCs over rituximab and GCs.	5, 6, 10	Very low to low
Recommendation: For patients with newly diagnosed active, severe PAN who are unable to tolerate cyclophosphamide, we conditionally recommend treating with other non-GC immunosuppressive agents and GCs over GCs alone.	8	Very low
Recommendation: For patients with newly diagnosed active, nonsevere PAN, we conditionally recommend treating with non-GC immunosuppressive agents and GCs over GCs alone.	12	Very low
Recommendation: In patients with newly diagnosed active, severe PAN, we conditionally recommend *against* using plasmapheresis combined with cyclophosphamide and GCs over cyclophosphamide and GCs alone.	7, 16	Low
Recommendation: For patients with PAN in remission who are receiving non-GC immunosuppressive therapy, we conditionally recommend discontinuation of non-GC immunosuppressive agents after 18 months over continued (indefinite) treatment.	13	Very low
Ungraded position statement: The optimal duration of GC therapy for PAN (e.g., tapering off by 6 months or longer than 6 months) is not well established, and thus, the duration of therapy should be guided by the patient's clinical condition, values, and preferences.	11	Very low
Treatment of refractory disease		
Recommendation: For patients with severe PAN that is refractory to treatment with GCs and non-GC immunosuppressive agents other than cyclophosphamide, we conditionally recommend switching the non-GC immunosuppressive agent to cyclophosphamide, over increasing GCs alone.	17	Very low
Remission maintenance		
Recommendation: For patients with newly diagnosed PAN who have achieved disease remission with cyclophosphamide, we conditionally recommend transitioning to another non-GC immunosuppressive agent over continuing cyclophosphamide.	9	Very low
Other considerations		
Recommendation: For patients with PAN with nerve and/or muscle involvement, we conditionally recommend physical therapy.	14	Very low
Recommendation: For patients with clinical manifestations of DADA2, we strongly recommend treatment with tumor necrosis inhibitors over GCs alone.	18	Low

* For the population, intervention, comparator, and outcome (PICO) questions used in the Grading of Recommendations Assessment, Development and Evaluation methodology, as developed for polyarteritis nodosa (PAN), please refer to Supplementary Appendix 2 (available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.24633/abstract). IV = intravenous; GCs = glucocorticoids; DADA2 = deficiency of adenosine deaminase 2.

vascular imaging, in tandem with clinical signs and pathology, helped validate the diagnosis (8) and determine disease severity (9). This in turn can influence treatment decisions. Moreover, obtaining vascular imaging at disease onset facilitates identification of new vascular involvement during disease relapse. Vascular imaging may not be warranted if patients present with isolated findings such as mononeuritis multiplex or myopathy, or if there are no clinical features suggestive of abdominal arterial involvement (such as absence of gastrointestinal or genitourinary symptoms, including renovascular hypertension). For children, clinicians should be mindful of minimizing repeated radiation exposure.

Clinicians currently use both conventional catheter-based dye angiography and noninvasive methods such as computed tomography (CT) or magnetic resonance (MR) angiography to diagnose PAN (10–12). Conventional angiography is the current gold standard due to its ability to provide better resolution, but it can be



Key recommendations for the treatment of polyarteritis nodosa (PAN)

associated with complications, albeit at a very low rate (13,14). However, the resolution for noninvasive modalities is improving, and CT or MR angiography may provide additional information regarding the vessel wall that conventional angiography does not. Specifically, CT angiography may enable visualization of more of the distal branches of the mesenteric arteries than MR angiography, but MR angiography may be preferred in certain clinical situations (e.g., need to avoid iodinated contrast). In patients with a negative CT or MR angiogram result with a high degree of suspicion for abdominal involvement, it is reasonable to consider conventional angiography.

Recommendation: For patients with a history of severe PAN with abdominal involvement who become clinically asymptomatic, we conditionally recommend follow-up abdominal vascular imaging.

Follow-up imaging permits assessment of disease control and treatment response. In the view of the Voting Panel, follow-up imaging is particularly important when baseline imaging demonstrates aneurysmal disease. The timing of follow-up imaging is dependent, in part, on clinical factors, such as the extent and severity of vascular abnormalities, overall disease course, and response to therapy. However, indefinite routine vascular imaging should be avoided if the abdominal vascular disease is shown to be quiescent.

Recommendation: For patients with suspected PAN involving the skin, we conditionally recommend obtaining a deep-skin biopsy specimen (i.e., a biopsy reaching the medium-sized vessels of the dermis) over a superficial skin punch biopsy to aid in establishing a diagnosis.

Indirect evidence (found in nonrandomized studies or studies in which findings were not primary aims) suggests that evaluation of deeper tissue is more effective at establishing a diagnosis of PAN (15,16), since a deeper-tissue sample is more likely to capture a medium-sized vessel. A deep-skin biopsy can be performed by a dermatologist as a deep (or "double") punch biopsy and does not necessarily require invasive resection. This recommendation had strong support from the Voting Panel but remains conditional due to limited evidence.

Recommendation: For patients with suspected PAN and peripheral neuropathy (motor and/or sensory), we conditionally recommend obtaining a combined nerve and muscle biopsy over a nerve biopsy alone to aid in establishing a diagnosis.

Several studies suggest an increased yield with nerve and concurrent muscle biopsy as opposed to nerve biopsy alone (15–19). However, the biopsy should sample involved tissue and not be performed "blind" (i.e., sampling tissue that does not appear

to be clinically affected). Of note, biopsy of an affected purely sensory nerve (e.g., sural nerve) is favored to avoid motor deficits.

Recommendation: For patients with a history of peripheral motor neuropathy secondary to PAN, we conditionally recommend serial neurologic examinations instead of repeated electromyography/nerve conduction studies (e.g., every 6 months) to monitor disease activity.

This recommendation is based on the opinion of the Voting Panel due to a lack of published evidence addressing the issue. Repeated electromyography in a patient with stable symptoms is *not* recommended due to the invasive nature of this study. However, repeated electromyography/nerve conduction study would be warranted if there were uncertainty as to whether a new (or worsening) process was developing.

Treatment of active disease

Recommendation: For patients with newly diagnosed active, severe PAN, we conditionally recommend initiating treatment with intravenous (IV) pulse glucocorticoids over high-dose oral glucocorticoids.

In several single-arm and comparative studies, evaluations of medical therapy were confounded by the use of other medications and did not control for IV pulse or high-dose oral glucocorticoid use (20–22). However, for active and severe disease specifically, patients may benefit from the additional mechanism of action of high-dose pulse glucocorticoids. That is, glucocorticoids may rapidly alter cell membrane and receptor function to promote suppression of inflammation once the glucocorticoid receptor is saturated (23). The Voting Panel noted that this recommendation was focused on patients with active, severe disease. For many patients with disease that is not associated with life-threatening manifestations (such as immediate risk of visceral infarct), oral glucocorticoids would be preferred due to lower overall glucocorticoid burden. For pediatric patients, pulse glucocorticoid therapy in other systemic immune disorders appears to have a favorable side-effect profile and is not more strongly associated with infections or other morbidities compared to oral glucocorticoids (24).

Recommendation: For patients with newly diagnosed active, severe PAN, we conditionally recommend initiating treatment with cyclophosphamide and high-dose glucocorticoids over high-dose glucocorticoids alone.

In newly diagnosed severe PAN, a single observational study and indirect evidence suggest that the use of cyclophosphamide has more benefits than glucocorticoid therapy alone, with no differences seen between oral and IV cyclophosphamide (25,26). Moreover, the use of additional cyclophosphamide cycles may provide a medium-term protection (3 years) against disease relapse, although this benefit wanes by 10 years (21). Use of cyclophosphamide may mitigate glucocorticoid toxicity by decreasing the cumulative steroid dose (27).

Recommendation: For patients with newly diagnosed active, severe PAN, we conditionally recommend initiating treatment with cyclophosphamide and glucocorticoids over rituximab and glucocorticoids.

While case reports have recently raised the question about the efficacy of rituximab use in PAN (28–30), its efficacy in PAN remains uncertain due to the lack of comparative or large single-arm studies in this disease.

Recommendation: For patients with newly diagnosed active, severe PAN who are unable to tolerate cyclophosphamide, we conditionally recommend treating with other nonglucocorticoid immunosuppressive agents and glucocorticoids over glucocorticoids alone.

Indirect evidence (i.e., data obtained from secondary outcomes in prior trials [25,31]) suggests that the combination of nonglucocorticoid immunosuppressive agents, such as azathioprine or methotrexate, with glucocorticoids is superior to glucocorticoids alone. Mycophenolate mofetil has not been well studied in PAN. No direct trials comparing glucocorticoid monotherapy with nonglucocorticoid combination therapy are available. In general, patients with severe PAN should be treated with cyclophosphamide over other immunosuppressive agents (26), but in patients unable to tolerate cyclophosphamide, another agent, such as azathioprine or methotrexate, is recommended over glucocorticoid monotherapy. Use of nonglucocorticoid immunosuppressive therapy may provide a glucocorticoid-sparing effect and minimize glucocorticoid toxicity, which is particularly significant in pediatric populations.

Recommendation: For patients with newly diagnosed active, nonsevere PAN, we conditionally recommend treating with nonglucocorticoid immunosuppressive agents and glucocorticoids over glucocorticoids alone.

In cases of nonsevere disease, a patient's age, clinical condition, and their values and preferences are important factors in assessing treatment. Although some patients achieve disease remission while receiving glucocorticoids alone, a substantial number of patients ultimately require additional nonglucocorticoid therapy, usually azathioprine or methotrexate (20). This recommendation contradicts management recommendations based on the Five-Factor Score (32), in which patients without factors of severe disease can be treated with glucocorticoids alone. We favor the use of nonglucocorticoid therapy in nonsevere disease, since the addition of nonglucocorticoid therapy may minimize glucocorticoid use and subsequent toxicity.

Recommendation: In patients with newly diagnosed active, severe PAN, we conditionally recommend *against* using plasmapheresis combined with cyclophosphamide and glucocorticoids over cyclophosphamide and glucocorticoids alone.

In a single trial conducted in 1995, the use of plasmapheresis in PAN was evaluated, but a distinction between PAN and HBV-associated PAN was not made (33). Confidence intervals in this study were very wide. Thus, evidence supporting the use of plasmapheresis in non–HBV-associated PAN is unavailable and the benefit unclear. Plasmapheresis may be considered in catastrophic cases unresponsive to the recommended aggressive immunosuppressive therapies and may have a role in the management of HBV-related PAN.

Recommendation: For patients with PAN in remission who are receiving nonglucocorticoid immunosuppressive therapy, we conditionally recommend discontinuation of nonglucocorticoid immunosuppressive agents after 18 months over continued (indefinite) treatment.

Evidence for this recommendation is based on a single study that was performed in 1979 (31). Although a significant number of patients with PAN have disease relapse, the majority experience monophasic disease (20). Indefinite treatment may therefore not be needed. Disease needs to be in sustained remission (Table 1) before discontinuing therapy.

Ungraded position statement: The optimal duration of glucocorticoid therapy for PAN (e.g., tapering off by 6 months or longer than 6 months) is not well established, and thus, the duration of therapy should be guided by the patient's clinical condition, values, and preferences.

In PAN, studies to determine the optimal length of time for glucocorticoid use have not been performed. In studies of other types of vasculitis (34), faster tapers led to more flares, which were often not organ-threatening and may have been mild. The Patient Panel preferred a longer taper, as a primary concern was disease control rather than glucocorticoid toxicity. Thus, duration of glucocorticoid use should be influenced by the patient's clinical condition, values, and preferences.

Treatment of refractory disease

Recommendation: For patients with severe PAN that is refractory to treatment with glucocorticoids and nonglucocorticoid immunosuppressive agents other than cyclophosphamide, we conditionally recommend switching the nonglucocorticoid immunosuppressive agent to cyclophosphamide over increasing glucocorticoids alone.

Based on the effectiveness of cyclophosphamide in new-onset severe PAN (26), indirect evidence suggests that cyclophosphamide should be used in patients with PAN that has evolved from a nonsevere presentation to one that is severe and does not adequately respond to other immunosuppressive agents.

Remission maintenance

Recommendation: For patients with newly diagnosed PAN who have achieved disease remission with cyclophosphamide, we conditionally recommend transitioning to another nonglucocorticoid immunosuppressive agent over continuing cyclophosphamide.

Due to its toxicity, cyclophosphamide therapy should not continue indefinitely and should generally be limited to 3–6 months per course (21). Based on the experience in antineutrophil cytoplasmic antibody–associated vasculitis, transitioning to another less toxic agent such as methotrexate or azathioprine is recommended once disease remission has been attained. Given the lack of clinical trials investigating remission maintenance in PAN, this recommendation was based on expert experience.

Other considerations

Recommendation: For patients with PAN with nerve and/or muscle involvement, we conditionally recommend physical therapy.

Indirect evidence for PAN is available for this recommendation from studies in inflammatory myositis. Based on this, we conditionally recommend this intervention due to its potential benefit and minimal risk. Physical therapy may be more beneficial for those with more substantial motor involvement. Patients on the Voting Panel expressed a high degree of enthusiasm for physical therapy as a modality for recovery and rehabilitation, in that they felt they had personally experienced benefit from physical therapy.

Recommendation: For patients with clinical manifestations of deficiency of adenosine deaminase 2 (DADA2), we strongly recommend treatment with tumor necrosis factor inhibitors over glucocorticoids alone.

DADA2 was first described in a series of patients with an early-onset (often childhood) PAN-like vasculitis (35). DADA2 is characterized by recurrent strokes and skin changes and diagnosed using *ADA2* sequencing or ADA2 functional assays, and ADA2 mutations have been identified in patients diagnosed as having systemic PAN (36). Although only 1 case series has been published, the strong signal of benefit of tumor necrosis inhibitors provides evidence that treatment with tumor necrosis inhibitors, instead of conventional immunosuppressive agents such as cyclophosphamide, prevents strokes (35,37). Thus, physicians should consider DADA2 in the setting of a PAN-like syndrome with

strokes, and if confirmed, we strongly recommend use of tumor necrosis factor inhibitors. The Voting Panel voted for a strong recommendation despite the small number of cases, stressing the prevention of severe adverse events.

DISCUSSION

This is the first guideline issued by the ACR, in conjunction with the VF, for the management of systemic PAN. These recommendations constitute a guide to help physicians treat patients with this disease. Because many recommendations are conditional, a patient's clinical condition, values, and preferences should influence the management decisions that are made. These recommendations should not be used by any agency to restrict access to therapy or require that certain therapies be utilized prior to other therapies.

Classic systemic PAN, although rare, remains a disease with a high mortality rate (22). Therefore, recommendations in this guideline indicate that patients with severe disease should be treated with cyclophosphamide and glucocorticoids. However, when patients present with nonsevere disease (i.e., without life- or organ-threatening manifestations such as renal insufficiency and tissue ischemia), use of alternative immunosuppressive agents and a glucocorticoid-sparing regimen is reasonable for remission induction. Use of diagnostic procedures such as angiography, electromyography/nerve conduction studies, and nerve and muscle biopsy is recommended to aid in diagnosis. However, the use of routinely repeated procedures during periods of disease quiescence is discouraged.

PAN has become increasingly rare, and no large clinical trials that focused solely on idiopathic (non–HBV-associated) PAN have been published. In addition, studies of PAN conducted prior to the recognition of microscopic polyangiitis may have included such patients and should be interpreted with caution. Many recommendations were based on expert experience of the Voting Panel and/or trials that were performed several years and, in some cases, decades ago. Strong recommendations will require larger interventional studies but will be challenging to conduct due to the rarity of this disease.

The process of developing these guidelines has brought to our attention other gaps in our understanding of the optimal treatment for PAN. These gaps include the role of longitudinal vascular imaging studies, the comparative effectiveness of nonglucocorticoid immunosuppressive agents, and the lack of biomarkers to inform disease activity or treatment response. Therefore, we encourage continued research in this disease. Future study and specific areas to investigate include the following: 1) determining how informative longitudinal vascular imaging is for assessing disease activity and determining disease prognosis; 2) conducting randomized clinical trials (including comparative efficacy trials) to assess the efficacy of nonglucocorticoid immunosuppressive agents, as well as identifying the optimal dosing, duration, and population that would benefit from these agents; 3) developing novel, targeted, and/or glucocorticoid-sparing therapies with minimal toxicity; and 4) identifying biomarkers to inform assessment of disease activity and prognosis.

In summary, the ACR and the VF present these recommendations to assist physicians in managing PAN, and this guideline can serve as a touchstone for basic principles of management. We hope this guideline will evolve as new research is conducted and new diagnostic and treatment strategies for PAN are identified.

ACKNOWLEDGMENTS

We thank Anne M. Ferris, MBBS, Ora Gewurz-Singer, MD, Rula Hajj-Ali, MD, Eric Matteson, MD, MPH, Robert F. Spiera, MD, Linda Wagner-Weiner, MD, MS, and Kenneth J. Warrington, MD, for serving on the Expert Panel. We thank Antoine G. Sreih, MD, and Gary S. Hoffman, MD, MS, for their contributions during the early phases of this project as members of the Core Team. Dr. Hoffman's participation ended July 2018 due to personal reasons. Dr. Sreih's involvement ended in December 2018 when he became primarily employed by industry, which precluded his continued participation in this project. We thank Joyce Kullman (Vasculitis Foundation) for her assistance with recruitment for the Patient Panel. We thank the patients who (along with authors Kathy A. Full and Omar I. Vitobaldi) participated in the Patient Panel meeting: Jane Ascroft, Scott A. Brunton, Dedra DeMarco, Thomas Fitzpatrick, Jenn Gordon, Maria S. Mckay, Sandra Nye, Stephanie Sakson, and Ben Wilson. We thank Robin Arnold, Catherine E. Najem, MD, MSCE, and Amit Aakash Shah, MD, MPH, for their assistance with the literature review. We thank the ACR staff, including Ms Regina Parker, for assistance in organizing the face-to-face meeting and coordinating the administrative aspects of the project, and Ms Robin Lane for assistance in manuscript preparation. We thank Ms Janet Waters for help in developing the literature search strategy and performing the initial literature search, and Ms Janet Joyce for performing the update searches.

AUTHOR CONTRIBUTIONS

All authors were involved in drafting the article or revising it critically for important intellectual content, and all authors approved the final version to be published. Drs. Chung and Gorelik had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Study conception and design. Chung, Gorelik, Langford, Maz, Abril, Guyatt, Archer, Full, Grayson, Merkel, Seo, Stone, Sule, Sundel, Vitobaldi, Turner, Mustafa.

Acquisition of data. Chung, Gorelik, Langford, Maz, Abril, Full, Imundo, Kim, Merkel, Stone, Vitobaldi, Byram, Dua, Husainat, James, Kalot, Lin, Springer, Turgunbaev, Villa-Forte, Turner, Mustafa.

Analysis and interpretation of data. Chung, Gorelik, Langford, Maz, Abril, Archer, Conn, Full, Grayson, Ibarra, Imundo, Kim, Merkel, Rhee, Seo, Stone, Vitobaldi, Warner, Byram, Dua, Husainat, Kalot, Lin, Springer, Turgunbaev, Mustafa.

This criteria set has been approved by the European League Against Rheumatism (EULAR) Executive Committee and the American College of Rheumatology (ACR) Board of Directors as Provisional. This signifies that the criteria set has been quantitatively validated using patient data, but it has not undergone validation based on an external data set. All EULAR/ACR-approved criteria sets are expected to undergo intermittent updates.

The American College of Rheumatology is an independent, professional, medical and scientific society which does not guarantee, warrant, or endorse any commercial product or service.

The objective of this study was to develop European League Against Rheumatism/American College of Rheumatology classification criteria for polymyalgia rheumatica (PMR). Candidate criteria were evaluated in a 6-month prospective cohort study of 125 patients with new-onset PMR and 169 non-PMR comparison

This article is published simultaneously in the April 2012 issue of *Annals of the Rheumatic Diseases*.

subjects with conditions mimicking PMR. A scoring algorithm was developed based on morning stiffness >45 minutes (2 points), hip pain/limited range of motion (1 point), absence of rheumatoid factor and/or anti–citrullinated protein antibody (2 points), and absence of peripheral joint pain (1 point). A score ≥4 had 68% sensitivity and 78% specificity for discriminating all comparison subjects from PMR. The specificity was higher (88%) for discriminating shoulder conditions from PMR and lower (65%) for discriminating RA from PMR. Adding ultrasound, a score ≥5 had increased sensitivity to 66% and specificity to 81%. According to these provisional classification criteria, patients ≥50 years old presenting with bilateral shoulder pain, not better explained by an alternative pathology, can be classified as having PMR in the presence of morning stiffness >45 minutes, elevated C-reactive protein and/or erythrocyte sedimentation rate, and new hip pain. These criteria are not meant for diagnostic purposes.

Polymyalgia rheumatica (PMR) is a common inflammatory rheumatic disease of older individuals and a common indication for long-term corticosteroid therapy (1–3). PMR is also subject to wide variations of clinical practice, due to the considerable uncertainty related to diagnosis, course, and management in primary and secondary care (4–7). There is no diagnostic laboratory test, inflammatory markers are not specific, and clinicians often turn to the corticosteroid response as a "test of treatment" to establish the diagnosis (1,2,8).

Difficulties in diagnosing and classifying patients with PMR are inherent in its definitions (9,10). The proximal pain and stiffness syndrome can occur at presentation in many other rheumatologic inflammatory illnesses in older people (1,2,7,9). Approximately half of patients diagnosed with PMR may have distal manifestations such as peripheral arthritis, hand swelling with pitting edema, and carpal tunnel syndrome (1,2,7,11). Polymyalgic presentation is common in late-onset rheumatoid arthritis (RA) and spondylarthritis and is also associated with giant cell arteritis in 10–30% of cases (1,2). Heterogeneity in the disease course, uncertainty regarding disease assessment parameters, and evolution of alternative diagnoses on followup complicate the management of PMR (9,12–15). For the above reasons a safe and specific approach preferring a relative underdiagnosis to an overdiagnosis is needed in PMR (9,11).

Uniform responsiveness to low doses of corticosteroids has been assumed to be a cardinal feature of PMR. However, there is little hard evidence to substantiate this assertion. A previous report showed that 3 weeks after starting prednisolone 15 mg a day only 55% showed a complete response to therapy (10). This also emphasizes that clinical trials of novel effective agents are needed in PMR.

The lack of standardized classification criteria has been a major factor hampering the development of rational therapeutic approaches (12,16,17) and causing difficulties in evaluating patients in clinical studies. In response to a European League Against Rheumatism (EULAR)/American College of Rheumatology (ACR) initiative, a criteria development work group convened in 2005.

A systematic literature review, a 3-phase hybrid consensus process, and a wider survey were undertaken to identify candidate criteria items (18). The first stage

Submitted for publication June 21, 2011; accepted in revised form October 31, 2011.

consisted of a meeting of 27 international experts who anonymously rated 68 potential criteria identified through literature review. In the second round the experts were provided with the results of the first round and re-rated the criteria items. In the third round the wider acceptance of the chosen criteria (>50% support) was evaluated using a survey of 111 rheumatologists and 53 nonrheumatologists in North America and western Europe.

In round 3, over 70% of respondents agreed on the importance of 7 core criteria (all achieving 100% support in round 2). These were aged 50 years or older, symptom duration 2 weeks or longer, bilateral shoulder and/or pelvic girdle aching, duration of morning stiffness more than 45 minutes, elevated erythrocyte sedimentation rate (ESR), elevated C-reactive protein (CRP), and rapid corticosteroid response. More than 70% agreed on assessing pain and limitation of shoulder (84%) and/or hip (76%) motion, but agreement was low for peripheral signs (e.g., carpal tunnel syndrome, tenosynovitis, peripheral arthritis).

The group reached consensus on the need for a prospective cohort study to evaluate the disease course from presentation in patients included on the basis of proximal pain and stiffness, with evaluations over a 6-month period while receiving a standardized corticosteroid treatment regimen (7,18–25). The group also agreed to assess musculoskeletal ultrasound as part of the PMR classification criteria. In this paper, we present the results from this prospective study and propose new classification criteria for PMR.

STUDY DESIGN AND METHODS

Consensus decisions about study design. A priori, the work group decided that a specific approach should be adopted for classifying newly presenting patients with bilateral shoulder pain as PMR (18). The group agreed on the following:

1. Patients presenting with polymyalgic syndrome should have stepwise evaluation on the basis of inclusion and exclusion criteria, response to a standardized corticosteroid challenge, and followup confirmation. The criteria items would be agreed-upon clinical features and laboratory investigations.

2. The need to standardize response to corticosteroid therapy in PMR. Because the goal of classification criteria is to identify patients for enrollment into clinical trials before any treatment, the response to corticosteroid therapy should be used in verifying the classification of a patient as having PMR, although it should not be used as a classification criterion. Because scientific evidence is poor as to what constitutes such a response it was agreed (>75% agreement) this response would be defined as >75% global response in clinical and laboratory parameters within 7 days of corticosteroid challenge with 15 mg oral prednisone or prednisolone and subsequent resolution of inflammatory indices (18).

3. That a prospective study would be needed to evaluate the disease course from presentation in patients included on the basis of the mandatory "core" criteria of proximal pain and stiffness. New-onset bilateral shoulder pain was selected as the main eligibility criterion as the percentage of PMR presenting with hip pain without shoulder pain was very small (<5%), and that as hip girdle pain is due to a wide range of conditions, it would require the enrollment of an impracticably large number of comparator patient groups (18). The study would evaluate at prespecified intervals symptoms, examination, investigations, and their evolution with standardized corticosteroid treatment in a prospective cohort of patients with new-onset bilateral shoulder pain (comparing the PMR case cohort with the comparator cohort of mimicking conditions) over a 6-month period.

4. Musculoskeletal ultrasound should be evaluated in a substudy as a feasible mode of investigation of possible PMR. A secondary objective of this substudy would be the evaluation of clinical and patient-based outcomes in PMR over a 6-month period (26,27).

Study population. The study was a prospective cohort study that included a cohort of patients with new-onset PMR and a comparison cohort of non-PMR patients with various conditions mimicking PMR. Study subjects were recruited from 21 community-based and academic rheumatology clinics in 10 European countries and the USA. Inclusion criteria for PMR patients were age 50 years or older, new-onset bilateral shoulder pain, and no corticosteroid treatment (for any condition) within 12 weeks before study entry, fulfilling all the inclusion and exclusion criteria defined in our previous report and in accordance with the judgment of the participating investigator that the patient had PMR (18). Every effort was made to choose patients across the spectrum of disease severity. Corticosteroid treatment for PMR patients was initiated according to a predefined treatment protocol starting with 15 mg a day oral prednisone for weeks 1 and 2, 12.5 mg a day for weeks 3 and 4, 10 mg a day for weeks 6–11, 10 mg/7.5 mg every other day for weeks 12–15, 7.5 mg a day for weeks 16–25, and tapering according to treatment response from week 26 onward. The gold standard for the pre-steroid diagnosis of PMR was established as above at presentation and when the diagnosis was maintained without an alternative diagnosis at week 26 of followup.

The non-PMR comparison cohort included conditions representative of the types that need to be distinguished from PMR, in both primary and secondary care. Inclusion criteria for the non-PMR comparison cohort were age 50 years or older, new-onset bilateral shoulder pain, and a diagnosis of either inflammatory or noninflammatory conditions, including new-onset RA, connective tissue diseases, various shoulder conditions (e.g., bilateral rotator cuff syndrome and/or adhesive capsulitis, rotator cuff tear, glenohumeral osteoarthritis), fibromyalgia, generalized osteoarthritis, and others. Patients known to have the condition for >12 weeks before the baseline evaluation (except fibromyalgia and chronic pain) were not eligible for inclusion. PMR patients with clinical suspicion of giant cell arteritis were included as part of the comparison cohort because these patients required different corticosteroid doses. Patients in the comparison cohort were included on the

basis of clinician diagnosis and not on formal criteria. No guidelines were provided for treatment of the conditions in the comparison cohort.

Ethics board approval was obtained at all participating institutions before initiation of the study, and all participants gave written informed consent before enrollment.

Followup and data collection. PMR patients were evaluated at baseline, and at 1, 4, 12, and 26 weeks. At each followup visit, clinical evaluation included response to corticosteroid therapy and opinion on the emergence of alternative diagnoses. Patients not considered as having PMR at any time were evaluated and treated according to accepted clinical practice. They were excluded from the PMR cohort and included in the non-PMR comparison cohort. Patients in the comparison cohort were evaluated at baseline and at 26 weeks.

Data were collected using standardized data collection forms and questionnaires translated into national languages. Data collection included the candidate inclusion/exclusion criteria items for classification of PMR, physical examination, and assessment of corticosteroid response. Criteria items were age 50 years or older, symptom duration 2 weeks or more, bilateral shoulder and/or pelvic girdle aching, recent weight loss >2 kg, duration of morning stiffness >45 minutes, elevated ESR, elevated CRP, and rapid response of symptoms to corticosteroids (>75% global response within 1 week to prednisolone/prednisone 15–20 mg a day). Pain was assessed using a horizontal 100-mm visual analog scale (VAS) in 4 separate locations (shoulder, pelvic, neck, and overall) with 0 indicating no pain and 100 indicating worst pain. Morning stiffness (in the past 24 hours) was assessed in minutes; functional status and quality of life were assessed by the modified Health Assessment Questionnaire (M-HAQ) and Short Form 36. A 100-mm VAS was also used for recording global well-being measures (patient and physician global) and fatigue. Physical examination included the presence or absence of tenderness, pain on movement, and limitation of the shoulders and hips. Aspects of corticosteroid therapy including dose, therapeutic response, and change in dose and therapy discontinuation were documented.

Data regarding laboratory measures (including ESR, CRP, rheumatoid factor [RF], and anti–citrullinated protein antibody [ACPA]) were obtained from clinically ordered tests performed at each study center. As the laboratory assays used at each center varied, test results were classified as normal/abnormal using the reference ranges from each center (see Supplementary Table 1, available on the *Arthritis & Rheumatism* web site at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)1529-0131). Both PMR and non-PMR subjects underwent ultrasound evaluation of shoulders and hips at baseline and at 26 weeks. Evaluations were made according to EULAR guidelines (28) to assess for features previously reported to be associated with PMR, including bicipital tenosynovitis, subacromial and subdeltoid bursitis, trochanteric bursitis, and glenohumeral and hip effusion. A rheumatologist or radiologist experienced in musculoskeletal ultrasound performed the ultrasound examination using linear probes with the frequency range 6–10 MHz for shoulders and linear or curved array probes with the frequency range 5–8 MHz for hips.

Statistical analysis. Descriptive statistics (means, percentages, etc.) were used to summarize the candidate criteria data. Demographics (age and gender) and candidate criteria were compared between PMR and comparison subjects using chi-square and rank sum tests. Several statistical approaches were considered in order to develop a scoring algorithm for PMR and to assess the proposed classification criteria in patients judged by expert clinician investigators to have PMR 26 weeks after enrollment (29).

First, logistic regression models to distinguish PMR patients from all comparison subjects and each subset of comparison subjects were examined. The C statistic, a measure of concordance analogous to the area under the receiver operating characteristic curve, was used to assess the ability of each individual criterion to distinguish between PMR and comparison subjects. The C statistic ranges from 0.5 to 1, with 0.5 indicating a criterion that provides no information. The sensitivity, specificity, and the positive and negative likelihood ratios were also examined.

Second, exploratory factor analysis was used to examine the interdependencies between the candidate criteria (30). Maximum-likelihood factor analysis with varimax rotation was used. Maximum-likelihood tests were used to examine goodness of fit (e.g., to determine the number of factors). This method is thought to be superior to the eigenvalue >1 or Cattell's scree plot method for selecting the number of factors (30). For each factor, variables with factor loadings >0.5 were examined and found to represent a similar domain. This technique allowed a reduction of the number of variables, as one variable from each factor was examined in multivariable logistic regression models. In addition, to avoid discarding a relevant domain as identified by expert consensus, a few of the variables with factor loading between 0.4 and 0.5 were also considered in the multivariable models.

Classification trees including the variables determined by the factor analysis were also considered, but were not found to be optimal for distinguishing PMR from comparison subjects (31,32). An integer scoring algorithm was defined based on the odds ratios in the final multivariable logistic regression model. Performance characteristics (sensitivity, specificity, etc.) of this scoring algorithm were assessed. In addition, the utility of ultrasound assessments for classifying PMR patients was examined using factor analysis and adding potential ultrasound criteria to the scoring algorithm. Odds ratios for clinical criteria varied somewhat in the scoring algorithm that included ultrasound criteria. Scoring weights based on both models were considered and found to perform similarly, so a common set of scoring weights was used for the clinical items in both algorithms in order to ease comparison and application of the criteria.

Finally, gradient boosting regression tree models, which are a machine learning technique, were examined to determine whether a better prediction could be achieved using a more complex algorithm (33).

RESULTS

At baseline, 128 patients were recruited into the PMR cohort and 184 patients were recruited into the non-PMR comparison cohort. During followup, 10 PMR patients were reclassified as not having PMR and moved into the non-PMR cohort. Similarly, 8 non-PMR com-

† Bilateral rotator cuff syndrome and/or adhesive capsulitis, rotator cuff tear, glenohumeral osteoarthritis.
‡ Data not available on all subjects.

parison cohort patients were reclassified as having PMR and moved into the PMR cohort. In addition, 7 patients (1 PMR and 6 non-PMR) were excluded due to missing information, and 2 non-PMR subjects with age <50 years and 9 non-PMR subjects with no shoulder pain were also excluded. Therefore, the final analysis was based on 125 PMR and 169 non-PMR subjects.

The diagnoses of the 169 non-PMR subjects (see Supplementary Table 2, available on the *Arthritis & Rheumatism* web site at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)1529-0131) were new-onset RA (49 [29%]), new-onset other seronegative arthritis (20 [12%]), new-onset connective tissue diseases or vasculitis (9 [5%]), shoulder conditions (52 [31%]), chronic pain (26 [15%]), infection (5 [3%]), previously undiagnosed malignancy (4 [2%]), and 2 each of endocrinopathy and neurologic disorders.

The distribution of the candidate classification criteria for the 125 PMR patients and 169 non-PMR comparison subjects (all, RA only, and shoulder condition only) is displayed in Table 1. Criteria items present in >80% of the PMR subjects were ≥2 weeks duration of symptoms, bilateral shoulder pain, and elevated CRP and/or ESR. Relevant clinical features that best discriminated RA from PMR were peripheral synovitis, the presence of RF and/or ACPA, and hip pain/limited range of motion. Features best discriminating shoulder conditions from PMR were hip pain/limited range of motion, morning stiffness, and elevated CRP and/or ESR.

Development of a scoring algorithm. Table 2 shows the results of univariate logistic regression models to distinguish PMR from all comparison subjects, RA only, and shoulder conditions only. Criteria items related to hip involvement (pain, tenderness, limited movement) had significant ability to discriminate PMR from all comparison subjects, RA, and shoulder conditions based on the C statistic. Early morning stiffness, M-HAQ, weight loss, and raised laboratory markers of inflammation distinguished PMR from comparison subjects, particularly those with shoulder conditions. The presence of ACPA and/or RF, peripheral synovitis, and joint pains had significant ability (with high C statistic) to distinguish PMR from RA. In addition, the odds

Table 2. Univariate logistic regression models to distinguish subjects with PMR from comparison subjects*

M-HAQ (per 1-unit increase)	2.3 (1.6–3.4)	0.66	1.3 (0.7–2.2)	0.55	6.7 (3.2–14)	0.78

* PMR = polymyalgia rheumatica; 95% CI = 95% confidence interval; RA = rheumatoid arthritis; CRP = C-reactive protein; ESR = erythrocyte sedimentation rate; RF = rheumatoid factor; ACPA = anti–citrullinated protein antibody; M-HAQ = modified Health Assessment Questionnaire.
† Bilateral rotator cuff syndrome and/or adhesive capsulitis, rotator cuff tear, glenohumeral osteoarthritis.

ratios for abnormal CRP and/or ESR were particularly high. This resulted because only 5 PMR patients did not have abnormal CRP and/or ESR, perhaps reflecting that the diagnosis of PMR is less certain in the presence of normal CRP and ESR. Therefore, abnormal CRP or ESR would be included as a required criterion in the scoring algorithm for PMR. Similarly, as all subjects in the study were required to have shoulder pain, this was also included as a required criterion for PMR.

Factor analysis revealed that 4 factors were sufficient to represent all the criteria (see Supplementary Table 3, available on the *Arthritis & Rheumatism* web site at http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)1529-0131). These 4 factors were hip pain/tenderness, peripheral synovitis or other joint pain, morning stiffness, and shoulder tenderness. Note that duration of symptoms, neck aching, carpal tunnel syndrome, weight loss, presence of RF/ACPA, and M-HAQ did not play a prominent role in any of the factors.

Next, multivariable logistic regression models were used to determine the importance of each criterion when assessed simultaneously (Table 3). Three models

Table 3. Multivariable logistic regression models*

§ $P = 0.008$.
¶ $P = 0.009$.

were considered: 1) including the 4 factors identified in factor analysis; 2) removing shoulder tenderness and adding presence of RF/ACPA; and 3) subsequently adding M-HAQ. While the subsequent additions appeared to be significant, they also negatively impacted the hip pain criteria. The utility of the inclusion of M-HAQ was questionable, as hip pain was easier to assess than M-HAQ in a clinical setting. Therefore, the second model, which included hip pain, other joint pain, morning stiffness, and abnormal RF/ACPA, was deemed the best multivariable model.

Additional analyses were performed using classification trees and assessing combinations of criteria. Classification trees were examined using 3 sets of potential variables: 1) the 4 identified factors; 2) adding presence of RF/ACPA; and 3) subsequently adding M-HAQ. The resulting trees were deemed inadequate. For example, the second tree, which was fit using the same 5 variables that were included in our scoring algorithm, had a sensitivity of 66% and specificity of 66%. This specificity was lower than the scoring algorithm developed from the logistic models. In addition, this tree only included morning stiffness and absence of RF and/or ACPA, so it was inadequate because it excluded other domains deemed necessary for content validity. Content validity requires that the set of criteria identified is comprehensive. This was the case in all 3 trees. Therefore, classification trees were deemed to have poorer performance and content validity than the logistic regression models.

A scoring algorithm was developed (Table 4) based on the multivariable logistic regression model presented in Table 3 and included morning stiffness for >45 minutes (2 points), hip pain/limited range of motion (1 point), absence of RF and/or ACPA (2 points), and the absence of peripheral joint pain (1 point). The score was evaluated using all PMR subjects (including the 5 with normal CRP/ESR) and all comparison subjects. This was done to account properly for the influence of CRP/ESR on the performance of the scoring algorithm. A score of 4 or greater had 68% sensitivity and 78% specificity for discriminating all comparison subjects from PMR. The specificity was higher (88%) for discriminating shoulder conditions from PMR and lower (65%) for discriminating RA from PMR. The C statistic for the scoring algorithm was 81%. A total of 40 PMR patients (32%) and 38 comparison subjects (22%) were incorrectly classified. The positive predictive value was 69% and the negative predictive value was 77%. Supplementary Table 4 (http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)1529-0131) shows the sensitivity and specificity for all possible cut points of the scoring algorithm.

Finally, gradient boosting regression tree models, which are a model averaging technique, were examined to determine whether a better prediction could be

Table 5. Ultrasound findings in 120 patients with PMR, 154 comparison subjects (including 46 with RA and 47 with shoulder conditions), and 21 subjects without shoulder conditions*

* Values are percents. RA = rheumatoid arthritis.
† $P < 0.01$ compared with polymyalgia rheumatica (PMR).
‡ $P < 0.05$ compared with PMR.

achieved using a more complex algorithm. The resulting C statistic from the gradient boosting model was 80%, which was quite comparable to the results for our scoring algorithm. This indicated that we will not be able to make better predictions from these data with another modeling approach.

Ultrasound findings. Ultrasound was performed in 120 PMR subjects, 154 of the comparison subjects (including 46 with RA and 47 with shoulder conditions), and 21 additional controls (not included in our study cohorts) who did not have shoulder conditions. Patients with PMR were more likely to have abnormal ultrasound findings in the shoulder (particularly subdeltoid bursitis and biceps tenosynovitis), and somewhat more likely to have abnormal findings in the hips than comparison subjects as a group (Table 5). PMR could not be distinguished from RA on the basis of ultrasound, but could be distinguished from non-RA shoulder conditions and subjects without shoulder conditions.

Assessing the utility of ultrasound in classifying PMR. Factor analysis (see Supplementary Table 5, http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)1529-0131) revealed several strong factors potentially useful for classifying patients with PMR from the ultrasound data. The inclusion of ultrasound findings in the scoring algorithm resulted in improving the C statistic to 82%. A score of 5 or greater had 66% sensitivity and 81% specificity for discriminating all comparison subjects from PMR. The specificity was higher (89%) for discriminating shoulder conditions from PMR and lower (70%) for discriminating RA from PMR. A total of 41 PMR patients (34%) and 30 comparison subjects (19%) were incorrectly classified. The positive predictive value was 72% and the negative predictive value was 75%. Therefore, ultrasound findings were useful in discriminating PMR from shoulder conditions, but less so in discriminating PMR from RA. Table 4 also shows the scoring algorithm including the ultrasound criteria. Supplementary Table 4 (http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)1529-0131) shows the sensitivity and specificity for all possible cut points of the scoring algorithm.

Response to corticosteroids in PMR. Complete corticosteroid response at 4 weeks was seen in 71% of patients and the response was sustained in 78% of responders at 26 weeks. As expected by the plan for tapering of the corticosteroids, the median prednisone dose decreased from 15 mg at baseline to 5 mg at 26 weeks. Response to treatment (percentage improvement in global pain VAS at weeks 4 and 26) was highly correlated with percentage improvement in other VAS measures (correlation >0.5 and $P < 0.001$ at weeks 4 and 26), but was not correlated with percentage change in corticosteroid dose ($P = 0.20$ at week 4 and $P = 0.47$ at week 26). There was no association between the points obtained on either scoring algorithm and the response to corticosteroids at 4 weeks (Spearman correlation coefficient 0.09, $P = 0.38$ for the scoring algorithm including ultrasound) and 26 weeks (data not shown), indicating that corticosteroid response cannot be used as part of PMR classification.

We also reevaluated our risk score model for the scoring algorithm using only the PMR subjects who responded to corticosteroids. When the final risk score

model was recomputed using only the subset of subjects with PMR who responded to corticosteroids (and all of the comparison subjects), the odds ratios for each of the criteria remained essentially unchanged. In addition, the specificity was identical and the sensitivity increased by an insignificant amount (0.5%).

Blinded reevaluation of selected PMR patients and non-PMR controls. The reevaluation exercise showed that most candidate criteria items performed well in discriminating PMR patients from controls. However, a third of the sample of PMR patients/comparison subjects was difficult to classify. The high C statistic levels associated with the corticosteroid response and posttreatment CRP and ESR suggested that the uncertainty originated from the pivotal role of corticosteroids in the investigator assessment, in deciding whether a patient does or does not have PMR. It raises questions such as whether PMR always responds adequately to corticosteroids and whether polymyalgic RF-positive disease without peripheral synovitis can occur (see Supplementary Appendix [http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)1529-0131)] for details).

Table 6. PMR classification criteria scoring algorithm—required criteria: age ≥50 years, bilateral shoulder aching, and abnormal CRP and/or ESR*

	Points without US (0–6)	Points with US (0–8)†
Morning stiffness duration >45 minutes	2	2
Hip pain or limited range of motion	1	1
Absence of RF or ACPA	2	2
Absence of other joint involvement	1	1
At least 1 shoulder with subdeltoid bursitis and/or biceps tenosynovitis and/or glenohumeral synovitis (either posterior or axillary) and at least 1 hip with synovitis and/or trochanteric bursitis	NA	1
Both shoulders with subdeltoid bursitis, biceps tenosynovitis, or glenohumeral synovitis	NA	1

* A score of 4 or more is categorized as polymyalgia rheumatica (PMR) in the algorithm without ultrasound (US) and a score of 5 or more is categorized as PMR in the algorithm with US. CRP = C-reactive protein; ESR = erythrocyte sedimentation rate; RF = rheumatoid factor; ACPA = anti–citrullinated protein antibody; NA = not applicable.
† Optional ultrasound criteria.

DISCUSSION

This is the first international multicenter prospective study examining consensus-based candidate classification criteria for PMR proposed by an international work group. Findings indicate that patients 50 years of age or older presenting with new bilateral shoulder pain (not better explained by an alternative diagnosis) and elevated CRP and/or ESR can be classified as having PMR in the presence of morning stiffness of >45 minutes and new hip involvement (pain, tenderness, limited movement). The absence of peripheral synovitis or of positive RA serology increases the likelihood of PMR. While recognizing that RF particularly may be present in patients with PMR, the absence of RF serology is useful in distinguishing PMR from RA in older patients for classification purposes (18,34). Ultrasound findings of bilateral shoulder abnormalities (subacromial bursitis/bicipital tenosynovitis/glenohumeral effusion) or abnormalities in 1 shoulder and hip (hip effusion, trochanteric bursitis) may significantly improve the specificity of the clinical criteria. These criteria are not meant for diagnostic purposes and have not been tested as diagnostic criteria.

Newer concepts of PMR are revealed by this and other recent studies—heterogeneity at presentation and course, lack of uniform responsiveness to low-dose steroids, and overlap with inflammatory arthritis. However, we feel that at present these classification criteria provide a basic framework for developing clinical trials of novel therapies in PMR.

How should the PMR classification criteria be applied? The target population will be patients aged 50 years or older presenting with new-onset (<12 weeks) bilateral shoulder pain and abnormal acute-phase response. The criteria may only be applied to those patients in whom the symptoms are not better explained by an alternative diagnosis. Mimicking conditions include the inflammatory and noninflammatory conditions studied as comparators in this report.

Four clinical and laboratory criteria along with optional ultrasound criteria (Tables 4 and 6) can be applied to eligible patients to identify patients with PMR suitable for low-dose corticosteroid therapy. The scoring scale is 0–6 (without ultrasound) and 0–8 (with ultrasound). In the absence of competing diagnoses, a score of 4 or greater (without ultrasound), or 5 or greater (with ultrasound) is indicative of PMR. Patients with a score of less than 4 (based on clinical plus laboratory criteria) cannot be considered to have PMR. Ultrasound improves the specificity of PMR diagnosis, and shows particularly good performance in differentiating PMR from noninflammatory conditions and thus is a recommended investigation for PMR.

Classification criteria for PMR should be useful for identifying patients appropriate for enrollment into clinical trials of novel medications for the treatment of PMR, and studying long-term outcomes in more homogeneous patient cohorts. Our analyses indicate that even typical PMR patients at presentation may vary in their response to low-dose corticosteroid therapy, indicating that corticosteroid response is not reliable as a classification feature for PMR. This is similar to other rheumatic diseases such as RA, in which phenotypically similar patients may exhibit different responses to disease-modifying antirheumatic drugs.

Strengths and limitations. The strengths of the study relate to harnessing international effort to address a disease area subject to wide variation of practice, to develop agreement on the definition of what may or may not be treated as PMR and what needs further evaluation.

Our study methodology satisfies the ACR guidelines for the development of classification criteria for rheumatic diseases (35). The consensus-based candidate criteria were generated by a multispecialty international group whose views were supported by the results of a wide trans-Atlantic survey. The work group suggested a prospective study designed to separate PMR patients from comparison subjects in patients included on a single eligibility criterion (new bilateral shoulder pain in subjects $\geq$50 years).

This ensured an inception cohort longitudinal observational design wherein the PMR cohort could be compared with the comparison cohort at similar chronological time points of disease. All PMR patients were evaluated before treatment with corticosteroids, were treated with a standard corticosteroid schedule, and assessed at predetermined time points. Our study is in keeping with the EULAR/ACR goal of developing rheumatic disease classification criteria as opposed to diagnostic criteria. We focused on subjects with new-onset/incident disease, and a 6-month longitudinal followup allowed an accurate evaluation of the disease course and diagnoses. Previous criteria for PMR were developed using cross-sectional comparisons. Only 2 of the previous criteria were developed through an evaluative process (20,36). Neither had a definition of the "gold standard" diagnosis other than the physician considered the patient to have "unequivocal" PMR.

Another strength of our proposed classification criteria is the imaging component. Musculoskeletal ultrasound has promise due to widespread availability, feasibility, and good research evidence (18). The PMR work group standardized the examination of shoulders and hips by ultrasound for the purposes of the current study (37). Our findings indicate that ultrasound evaluation of hips and shoulders adds significantly to the evaluation of the polymyalgic syndrome. The lack of a "gold standard" and the challenge of circularity were addressed through a blinded multirater reevaluation exercise in selected cases and comparison subjects (see Supplementary Appendix [http://onlinelibrary.wiley.com/journal/10.1002/(ISSN)1529-0131)]). Most of the candidate criteria items performed well. The misclassification of several subjects reflects the difficulty in discriminating PMR from other inflammatory conditions such as RA. This uncertainty originates from the pivotal role of (and circular reasoning related to using) the corticosteroid response in deciding whether a patient does or does not have PMR. Although the proposed scoring algorithm has high specificity for identifying PMR patients, it is nevertheless unable to predict the subsequent corticosteroid response, suggesting heterogeneity of disease course and treatment response. This has also been reported previously (10,38).

While we were able to scrutinize the basis for PMR diagnosis, no formal criteria were required for diagnosis of the comparison conditions. This is a limitation of the study. However, the study was led in all centers by experienced rheumatologists with major clinical and research interest in PMR and related conditions. We did not include hip pain without shoulder pain as an eligibility criterion for reasons discussed in the Methods section. Funding constraints limited the followup duration to only 6 months. We were also limited by lack of funding for the central measurement of laboratory data. Values of ESR, CRP, RF, and ACPA were based on local laboratory assays. Our study approach reflects a pragmatic view, which perhaps lends wider applicability to the results of the study.

Our classification algorithm had a C statistic of 81%, which exceeds the threshold of 80% that is conventionally considered to be useful in clinical decision-making. However, we suggest that the criteria are regarded as provisional at this point, awaiting validation in a separate cohort.

In conclusion, patients aged 50 years or older presenting with bilateral shoulder pain and elevated CRP and/or ESR can be classified as having PMR in the presence of morning stiffness for more than 45 minutes, and new hip pain in the absence of peripheral synovitis or positive RA serology. Using ultrasound, a score of 5 or greater had 66% sensitivity and 81% specificity for discriminating all comparison subjects from PMR. In our view, this approach can now be used to test eligibility

for trials with newer therapies in PMR. A number of future research questions are highlighted, including: 1) Should PMR be considered as a part of the spectrum of late-onset inflammatory arthritis? 2) Can polymyalgic disease without peripheral synovitis occur in RF-positive disease? 3) Can we diagnose PMR in patients with normal acute-phase response? 4) What is the role of the early introduction of disease-modifying antirheumatic drugs in PMR?

We have collected and stored blood samples from both the case and the comparator groups in the study. We hope to develop research proposals using these biospecimens to test several candidate biomarkers in PMR. These proposals will also examine the acute-phase response: whether stratification of the response and differential levels of acute-phase reactants and cytokines may function as additional classification criteria items.

ACKNOWLEDGMENTS

The investigators would like to acknowledge EULAR, ACR, the Mayo Foundation, and the Biobanque de Picardie in Amiens, France, for material and intellectual support of this project. The investigators also wish to recognize the individual and uncompensated efforts of the staff at each participating institution, without which this study could not have been completed.

AUTHOR CONTRIBUTIONS

All authors were involved in drafting the article or revising it critically for important intellectual content, and all authors approved the final version to be published. Drs. Dasgupta and Matteson had full access to all of the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis.

2022 American College of Rheumatology/EULAR Classification Criteria for Takayasu Arteritis

Peter C. Grayson,[1] Cristina Ponte,[2] Ravi Suppiah,[3] Joanna C. Robson,[4] Katherine Bates Gribbons,[1] Andrew Judge,[5] Anthea Craven,[6] Sara Khalid,[6] Andrew Hutchings,[7] Debashish Danda,[8] Raashid A. Luqmani,[6] Richard A. Watts,[9] and Peter A. Merkel[10], for the DCVAS Study Group

This criteria set has been approved by the American College of Rheumatology (ACR) Board of Directors and the EULAR Executive Committee. This signifies that the criteria set has been quantitatively validated using patient data, and it has undergone validation based on an independent data set. All ACR/EULAR-approved criteria sets are expected to undergo intermittent updates.

The ACR is an independent, professional, medical and scientific society that does not guarantee, warrant, or endorse any commercial product or service.

Objective. To develop and validate new classification criteria for Takayasu arteritis (TAK).

Methods. Patients with vasculitis or comparator diseases were recruited into an international cohort. The study proceeded in 6 phases: 1) identification of candidate criteria items, 2) collection of candidate items present at diagnosis, 3) expert panel review of cases, 4) data-driven reduction of candidate items, 5) derivation of a points-based classification score in a development data set, and 6) validation in an independent data set.

Results. The development data set consisted of 316 cases of TAK and 323 comparators. The validation data set consisted of an additional 146 cases of TAK and 127 comparators. Age ≤60 years at diagnosis and imaging evidence of large-vessel vasculitis were absolute requirements to classify a patient as having TAK. The final criteria items and weights were as follows: female sex (+1), angina (+2), limb claudication (+2), arterial bruit (+2), reduced upper extremity pulse (+2), reduced pulse or tenderness of a carotid artery (+2), blood pressure difference between arms of ≥20 mm Hg (+1), number of affected arterial territories (+1 to +3), paired artery involvement (+1), and abdominal aorta plus renal or mesenteric involvement (+3). A patient could be classified as having TAK with a cumulative score of ≥5 points. When these criteria were tested in the validation data set, the model area under the curve was 0.97 (95% confidence interval [95% CI] 0.94–0.99) with a sensitivity of 93.8% (95% CI 88.6–97.1%) and specificity of 99.2% (95% CI 96.7–100.0%).

Conclusion. The 2022 American College of Rheumatology/EULAR classification criteria for TAK are now validated for use in research.

INTRODUCTION

Takayasu arteritis (TAK) is one of the major forms of large-vessel vasculitis (LVV) (1). TAK is a chronic disease defined by granulomatous inflammation affecting the aorta and its primary branches. Complications from vascular damage can result in substantial morbidity including stroke, myocardial infarction, mesenteric ischemia, and limb claudication.

Unlike diagnostic criteria, the purpose of classification criteria is to ensure that a homogenous population is selected for inclusion into clinical trials and other research studies (2). In 1990, the American College of Rheumatology (ACR) endorsed classification criteria for TAK (3). These criteria were developed using data from only 63 patients with TAK and have never been independently validated. Additionally, these criteria were derived using data from patients exclusively from North America without representation from Europe or Asia, where clinical patterns of disease may differ (4), limiting the generalizability of results. Given these constraints, the 1990 ACR criteria for TAK no longer satisfy accepted current standards (5) for classification criteria development, and updated criteria are warranted. Further highlighting a need for uniform, revised criteria in TAK is the use of divergent eligibility criteria to define study populations in 2 recent randomized clinical trials conducted in North America and Japan, making comparisons between the trial findings difficult (6,7).

Advancements in imaging techniques and the ongoing adoption of noninvasive vascular imaging approaches in clinical practice have broadened understanding of the clinical heterogeneity in LVV (8). Disease of the extracranial arteries is increasingly recognized in patients with giant cell arteritis (GCA), making the distinction between TAK and GCA more challenging (9). Age is typically used as a primary classifier to differentiate between TAK and GCA; however, specific age thresholds to define each disease have not been standardized. Therefore, in addition to incorporating data from a larger patient population from a wider geographic spectrum, the updated TAK classification criteria should reflect modern clinical practice, including current imaging techniques, and also define specific age thresholds.

This article outlines the development and validation of the new ACR/EULAR-endorsed classification criteria for TAK.

METHODS

An international Steering Committee comprising clinician investigators with expertise in vasculitis, statisticians, and data managers was established to oversee the overall development of classification criteria for primary vasculitis (10). A detailed and complete description of the methods involved in the development and validation of the classification criteria for TAK is located in Supplementary Appendix 1 (http://onlinelibrary.wiley.com/doi/10.1002/art.42324). Briefly, the Steering Committee implemented a 6-stage plan using data-driven and consensus methodology to develop the following criteria.

Stage 1: generation of candidate classification items for the systemic vasculitides. Candidate classification items were generated by expert opinion and reviewed by a group of vasculitis experts across a range of specialties using nominal group technique.

Stage 2: Diagnostic and Classification Criteria for Vasculitis (DCVAS) prospective observational study. A prospective, international, multisite observational study was conducted (see Appendix A for study investigators and sites). Ethical approval was obtained from local ethics committees. Consecutive patients representing the full spectrum of vasculitides were recruited from academic and community practices. Patients were included if they were 18 years or older and had a diagnosis of vasculitis or a condition that mimics vasculitis (e.g., infection, malignancy, atherosclerosis). Patients with TAK could only be enrolled within 5 years of diagnosis. Only data present at diagnosis were used to develop the classification criteria.

Stage 3: expert review to derive a gold standard–defined set of cases of LVV. Experts in vasculitis from a wide range of geographic locations and specialties (see Appendix A) reviewed all submitted cases of vasculitis and a random selection of vasculitis mimics. Each reviewer was asked to review ~50 submitted cases to confirm the diagnosis and to specify the degree of certainty of their diagnosis as follows: very certain, moderately certain, uncertain, or very uncertain. Only cases agreed upon with at least moderate certainty by 2 reviewers were retained for further analysis.

Stage 4: refinement of candidate items specifically for LVV. The Steering Committee conducted a data-driven process to reduce the number of candidate items of relevance to cases

and comparators for LVV. Density plots were assessed to study age distribution at diagnosis and symptom onset for TAK and GCA. Absolute age requirements versus incorporation of age as a candidate criteria item were considered. Items related to the vascular physical examination, vascular imaging, arterial biopsy, and laboratory values were combined or eliminated based on consensus review. Items were selected for exclusion if they had a prevalence of <5% within the data set, and/or they were not clinically relevant for classification criteria (e.g., related to infection, malignancy, or demography). Low-frequency items of clinical importance could be combined, when appropriate. Patterns of vascular imaging findings detected by vascular ultrasound, angiography, or positron emission tomography were defined by K-means clustering (11).

Stage 5: derivation of the final classification criteria for TAK. The DCVAS data set was split into development (70%) and validation (30%) sets. Comparisons were performed between cases of TAK and a randomly selected comparator group in the following proportions: GCA, 33.6%; other vasculitides that mimic GCA and TAK (isolated aortitis, primary central nervous system vasculitis, polyarteritis nodosa, Behçet's disease, and other LVV), 33.1%; a comparator mimic of LVV (e.g., headache syndrome or atherosclerosis), 33.3%. Least absolute shrinkage and selection operator (lasso) logistic regression was used to identify predictors from the data set and create a parsimonious model including only the most important predictors. The final items in the model were formulated into a clinical risk-scoring tool, with each factor assigned a weight based on its respective regression coefficient. A threshold that best balanced sensitivity and specificity was identified for classification.

Stage 6: validation of the final classification criteria for TAK. Performance of the new criteria was validated in an independent set of cases and comparators. Performance of the final classification criteria was examined in specific subsets of patients with TAK using data from the combined development and validation sets, to maximize sample sizes for the subgroups. Patients were studied according to different intervals of age at diagnosis to determine if the criteria performed well across the age spectrum of TAK. Performance characteristics of the new criteria were also tested in patients recruited into the DCVAS study from different regions of the world where prevalence of TAK and clinical assessment approaches may differ. Comparison was made between the measurement properties of the new 2022 ACR/EULAR classification criteria for TAK and the 1990 ACR classification criteria.

RESULTS

Generation of candidate classification items for the systemic vasculitides. The Steering Committee identified >1,000 candidate items for the DCVAS Case Report Form (Supplementary Appendix 2, http://onlinelibrary.wiley.com/doi/10.1002/art.42324).

DCVAS prospective observational study. Between January 2011 and December 2017, the DCVAS study recruited 6,991 participants from 136 sites in 32 countries. Information on the DCVAS sites, investigators, and study participants is listed in Supplementary Appendices 3, 4, and 5 (http://onlinelibrary.wiley.com/doi/10.1002/art.42324).

Expert review methodology to derive a gold standard–defined final set of cases of LVV. The LVV expert panel review process included 56 experts who reviewed vignettes derived from the Case Report Forms for 2,131 cases submitted with a diagnosis of LVV (1,608 [75.5% of Case Report Forms]), another type of vasculitis (118 [5.5% of Case Report Forms]), or a mimic of vasculitis (405 [19.0% of Case Report Forms]). Characteristics and the list of expert reviewers are shown in Supplementary Appendices 6 and 7 (http://onlinelibrary.wiley.com/doi/10.1002/art.42324). A sample vignette and the LVV expert panel review flow chart are shown in Supplementary Appendices 8 and 9. A total of 1,695 cases (80%) passed the main LVV process. An additional 373 cases of LVV and comparators, confirmed during a previous review process to derive the classification criteria for antineutrophil cytoplasmic antibody–associated vasculitis, were also included. In total, after both review processes, 2,068 cases were available for the stages 4 and 5 analyses.

The submitting physician diagnosis of TAK was confirmed in 500 of 610 cases (82.0%) after both expert panel reviews. The reasons for exclusion were diagnosis of TAK categorized as "uncertain" or "very uncertain" during panel review (n = 95) or change in diagnosis during panel review to another type of vasculitis (e.g., GCA, isolated aortitis, LVV that could not be subtyped) (n = 10) or to a comparator disease (n = 5). An additional 9 patients who were not initially diagnosed as having TAK by the submitting physician were diagnosed as having TAK after panel review and DCVAS Steering Committee member adjudication. Per Steering Committee consensus, imaging evidence of LVV was considered an absolute requirement to classify TAK. Of 509 cases confirmed by expert panel review, 47 patients with TAK did not have documented disease according to a vascular imaging study and were excluded from further analysis, leaving a total of 462 patients with TAK for subsequent analysis.

Refinement of candidate items specifically for TAK. Patients with TAK were diagnosed in the following age groups: 18–39 years (n = 355; 77%); 40–60 years (n = 104; 23%); and >60 years (n = 3; <1%) (see Supplementary Appendix 10 for the distribution of "age at diagnosis" in patients with LVV, and the similar distribution of "age at symptom onset," http://onlinelibrary.wiley.com/doi/10.1002/art.42324). Therefore, an age

23265205, 0, Downloaded from https://onlinelibrary.wiley.com/doi/10.1002/art.42324, Wiley Online Library on [28/11/2022]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of ≤60 years at diagnosis was considered an absolute requirement to classify a patient as having TAK.

Prevalence of arterial damage (stenosis, occlusion, or aneurysm) was greater in TAK compared to GCA in the following 9 arterial territories: thoracic aorta, abdominal aorta, left and right carotid, left and right subclavian, mesenteric, and left and right renal arteries (Supplementary Appendix 11, http://onlinelibrary.wiley.com/doi/10.1002/art.42324). Therefore, a composite variable representing the number of affected arteries was created based upon luminal damage in those 9 territories. As previously reported, cluster analyses identified vascular damage in the abdominal aorta and the renal or mesenteric arteries as a specific imaging pattern for TAK in the DCVAS cohort (11); thus, this arterial pattern was tested as a potential classifier of TAK (Supplementary Appendix 12, http://onlinelibrary.wiley.com/doi/10.1002/art.42324). Symmetric disease in branch arteries (carotid, subclavian, and renal arteries) was seen in 30.3% patients with TAK compared to 2.7% of the comparators ($P < 0.01$) and, therefore, was included as a potential classifier. A systolic blood pressure difference of ≥20 mm Hg between upper extremities optimized specificity to differentiate TAK from other forms of LVV.

Following a data-driven and expert consensus process, 72 items from the DCVAS Case Report Form were retained for lasso regression analysis, including 32 demographic and clinical items, 14 laboratory items (including values of C-reactive protein level and erythrocyte sedimentation rate, each divided into 5 categories), 14 imaging items (13 composite), 11 vascular examination items (5 composite, and upper extremity blood pressure divided into 6 categories), and 1 arterial biopsy item (Supplementary Appendix 13, http://onlinelibrary.wiley.com/doi/10.1002/art.42324). Criteria for TAK and GCA were independently derived from this common set of 72 items.

Derivation of the final classification criteria for TAK. Table 1 lists the demographic and disease features of the 462 patients with TAK and 450 comparators used to develop and validate the criteria, of which 316 patients with TAK and 323 comparators were in the development data set and 146 patients with TAK and 127 comparators were in the validation data set. The patients with TAK were recruited from Asia (n = 298), Europe (n = 130), North America (n = 28), Africa (n = 3), and Oceania (n = 3). Clinical diagnoses assigned to patients in the comparator group are detailed in Supplementary Appendix 14 (http://onlinelibrary.wiley.com/doi/10.1002/art.42324).

Lasso logistic regression analysis using all 72 items resulted in a model of 9 independent items (Supplementary Appendix 15B, http://onlinelibrary.wiley.com/doi/10.1002/art.42324). Weighting of individual criterion was based on logistic regression fitted to the 9 selected predictors. The number of affected arterial territories functioned as an almost perfect classifier (Supplementary Appendix 16B) and was thus also included in the final model, with criterion weighting determined by consensus of the Steering Committee (Supplementary Appendix 17B).

Validation of the final classification criteria for TAK. Using a cutoff of ≥5 in total risk score in the validation data set (see Supplementary Appendix 18B for cutoff points), the sensitivity was

Table 1. Demographic and disease features of the patients with Takayasu arteritis and the comparators*

	TAK (n = 462)	Comparators (n = 450)†	*P*

93.8% (95% confidence interval [95% CI] 88.6–97.1%), and the specificity was 99.2% (95% CI 96.7–100.0%). The area under the curve for the model was 0.97 (95% CI 0.94–0.99) (Supplementary Appendix 19B, http://onlinelibrary.wiley.com/doi/10.1002/art.42324). The final classification criteria for TAK are shown in Figure 1 (for the slide presentation versions, see Supplementary Figure 1, http://onlinelibrary.wiley.com/doi/10.1002/art.42324).

2022 AMERICAN COLLEGE OF RHEUMATOLOGY / EULAR

CLASSIFICATION CRITERIA FOR **TAKAYASU ARTERITIS**

CONSIDERATIONS WHEN APPLYING THESE CRITERIA

- **These classification criteria should be applied to classify the patient as having Takayasu arteritis when a diagnosis of medium-vessel or large-vessel vasculitis has been made**
- **Alternate diagnoses mimicking vasculitis should be excluded prior to applying the criteria**

ABSOLUTE REQUIREMENTS

Age ≤ 60 years at time of diagnosis	
Evidence of vasculitis on imaging[1]	

ADDITIONAL CLINICAL CRITERIA

Female sex	+1
Angina or ischemic cardiac pain	+2
Arm or leg claudication	+2
Vascular bruit[2]	+2
Reduced pulse in upper extremity[3]	+2
Carotid artery abnormality[4]	+2
Systolic blood pressure difference in arms ≥ 20 mm Hg	+1

ADDITIONAL IMAGING CRITERIA

Number of affected arterial territories (select one)[5]	
One arterial territory	+1
Two arterial territories	+2
Three or more arterial territories	+3
Symmetric involvement of paired arteries[6]	+1
Abdominal aorta involvement with renal or mesenteric involvement[7]	+3

Sum the scores for 10 items, if present. A score of ≥ 5 points is needed for the classification of TAKAYASU ARTERITIS.

1. Evidence of vasculitis in the aorta or branch arteries must be confirmed by vascular imaging (e.g., computed tomographic/catheter-based/magnetic resonance angiography, ultrasound, positron emission tomography).
2. Bruit detected by auscultation of a large artery, including the aorta, carotid, subclavian, axillary, brachial, renal, or iliofemoral arteries.
3. Reduction or absence of pulse by physical examination of the axillary, brachial, or radial arteries.
4. Reduction or absence of pulse of the carotid artery or tenderness of the carotid artery.
5. Number of arterial territories with luminal damage (e.g., stenosis, occlusion, or aneurysm) detected by angiography or ultrasonography from the following nine territories: thoracic aorta, abdominal aorta, mesenteric, left or right carotid, left or right subclavian, left or right renal arteries.
6. Bilateral luminal damage (stenosis, occlusion, or aneurysm) detected by angiography or ultrasonography in any of the following paired vascular territories: carotid, subclavian, or renal arteries.
7. Luminal damage (stenosis, occlusion, aneurysm) detected by angiography or ultrasonography involving the abdominal aorta and either the renal or mesenteric arteries.

Figure 1. The final 2022 American College of Rheumatology/EULAR Classification Criteria for Takayasu arteritis.

Table 2. Performance characteristics of the 2022 ACR/EULAR classification criteria for Takayasu arteritis*

Patient subset	Total no. patients (no. TAK patients)	Sensitivity (95% CI)	Specificity (95% CI)	AUC (95% CI)
Development data set	639 (316)	89.9 (86.0–93.0)	96.6 (94.0–98.3)	0.93 (0.91–0.95)
Validation data set	273 (146)	93.8 (88.6–97.1)	99.2 (96.7–100.0)	0.97 (0.94–0.99)
Age intervals				
18–39 years	437 (351)	94.0 (91.0–96.3)	97.7 (91.9–99.7)	0.96 (0.94–0.98)
40–60 years	226 (104)	83.7 (75.1–90.2)	91.8 (85.4–96.0)	0.88 (0.83–0.92)
World regions				
North America	127 (28)	85.7 (67.3–96.0)	92.9 (86.0–97.1)	0.89 (0.82–0.96)
Europe	422 (130)	91.5 (85.4–95.7)	94.9 (91.7–97.1)	0.93 (0.90–0.96)
North America/Europe combined	549 (158)	90.5 (84.8–94.6)	94.4 (91.6–96.4)	0.92 (0.90–0.95)
Asia	357 (298)	92.0 (88.3–94.8)	93.2 (83.5–98.1)	0.94 (0.89–0.96)

* Performance characteristics for the age and regional subsets were reported using data from the combined development and validation data sets to maximize sample size. ACR = American College of Rheumatology; TAK = Takayasu arteritis; 95% CI = 95% confidence interval; AUC = area under the curve.

The performance characteristics of the criteria in different subsets of patients with TAK are shown in Table 2 and Supplementary Appendix 20B. For patients who were diagnosed between 18 and 39 years of age, the sensitivity of the criteria was 94.0% (95% CI 91.0–96.3%), and the specificity was 97.7% (95% CI 91.9–99.7%). For patients who were diagnosed between 40 and 60 years of age, the sensitivity of the criteria was 83.7% (95% CI 75.1–90.2%), and the specificity was 91.8% (95% CI 85.4–96.0%). Because age restrictions are absolute requirements for the 2022 ACR/EULAR classification criteria for TAK (≤60 years at diagnosis) and GCA (≥50 years at diagnosis), patients with LVV between the ages of 50 and 60 years are potentially eligible to fulfill criteria for TAK and GCA. Of the 26 patients with TAK diagnosed between the ages of 50 and 60 years, 23 (88.5%) were classified correctly as having TAK, 1 (3.9%) was incorrectly classified as having GCA, and 1 (3.9%) fulfilled criteria for both TAK and GCA (Supplementary Appendix 21, http://onlinelibrary.wiley.com/doi/10.1002/art.42324). The criteria performed well in both Asia (sensitivity 92.0%, specificity 93.2%) and Europe/North America (sensitivity 90.5%, specificity 94.4%).

When the 1990 ACR classification criteria for TAK were applied to the DCVAS validation data set, the criteria performed poorly due to low sensitivity (84.3% [95% CI 77.3–89.7%]) but retained excellent specificity (99.2% [95% CI 95.7–100.0%]). In particular, the 1990 criteria had poor sensitivity for patients who were diagnosed as having TAK between 40 and 60 years of age (62.5% [95% CI 52.5–71.8%]).

DISCUSSION

Presented here are the final 2022 ACR/EULAR TAK classification criteria. A 6-stage approach was used, underpinned by data from the multinational, prospective DCVAS study and informed by expert review and consensus at each stage. The comparator group for developing and validating the criteria were other vasculitides and conditions that mimic TAK, where discrimination from TAK is difficult but important. In the validation data set, the new criteria had a sensitivity of 93.8% (95% CI 88.6–97.1%) and a specificity of 99.2% (95% CI 96.7–100.0%). These are the official final values that should be quoted when referring to the criteria. The sensitivity and specificity values calculated in the development data set were very similar, providing reassurance that the statistical methods avoided overfitting of models. Calculations of sensitivity and specificity for patient subgroups were made in the combined development and validation data sets to maximize sample sizes for the subgroups. Reassuringly, the new criteria for TAK have excellent sensitivity and specificity across different regions of the world. The criteria also incorporate modern imaging techniques, which are useful both to diagnose LVV and to differentiate among different types of vasculitis. The criteria were designed to have face and content validity for use in clinical trials and other research studies.

These criteria are validated and intended for the purpose of *classification* of vasculitis and are not appropriate for use to establish a *diagnosis* of vasculitis (2). The aim of the classification criteria is to differentiate cases of TAK from similar types of vasculitis in research settings (5). Therefore, *the criteria should only be applied when a diagnosis of large- or medium-vessel vasculitis has been made and all potential "vasculitis mimics" have been excluded*. For example, the criteria were not developed to differentiate patients with TAK from patients with atherosclerosis or noninflammatory genetic diseases that damage the large arteries. The 1990 ACR classification criteria for vasculitis perform poorly when used for diagnosis (i.e., when used to differentiate between cases of vasculitis versus mimics without vasculitis), and it is expected that the 2022 criteria would also perform poorly if used inappropriately as diagnostic criteria (12).

The 2022 ACR/EULAR TAK classification criteria reflect the collaborative effort of the international vasculitis community to delineate the salient clinical features that differentiate TAK from

23265205, 0, Downloaded from https://onlinelibrary.wiley.com/doi/10.1002/art.42324, Wiley Online Library on [28/11/2022]. other forms of vasculitis, most notably GCA. The final criteria include 10 clinical items that are routinely assessed during clinical evaluation of patients with TAK. The criteria highlight the importance of clinical symptoms, vascular physical examination, and vascular imaging as important disease classifiers. Features of TAK may differ in patients from different parts of the world (13). The 2022 ACR/EULAR TAK classification criteria retained excellent performance characteristics when tested in patients from different regions, including Asia where the disease is most prevalent (14). While TAK is often considered a disease of the young, 25% of the patients with TAK in the DCVAS cohort were older than 40 years at the time of diagnosis. Therefore, an age at diagnosis of ≤60 years, rather than a lower age threshold, was set as an absolute requirement for disease classification. The 2022 ACR/EULAR TAK classification criteria performed well when applied to patients ages 18–60 years and outperformed the 1990 ACR Classification Criteria for TAK in the subset of patients diagnosed as having TAK ages 40–60 years.

There are several strengths of the new 2022 ACR/EULAR TAK classification criteria. The criteria were developed by a large group of international experts in systemic vasculitis, with guidance from the ACR regarding modern methods of classification criteria development. The criteria represent several important methodologic advancements compared to the original 1990 ACR classification criteria for TAK. First, expert review rather than submitting physician diagnosis was used as the diagnostic reference standard to minimize investigator bias. Second, while the 1990 ACR criteria were entirely derived using data from 63 North American patients with TAK and not validated in a separate data set, the new criteria were developed in 316 patients with TAK and validated in an independent data set which contained an additional 146 patients with TAK from an international cohort. Third, unlike the 1990 ACR criteria, the new ACR/EULAR TAK criteria are weighted to reflect the relative importance of specific items (e.g., number of affected arterial territories). Finally, when both criteria sets were tested within the DCVAS cohort, the performance characteristics of the 2022 ACR/EULAR TAK criteria outperformed the 1990 ACR criteria.

There are some study limitations to consider. Acquisition of clinical and imaging data among patients with LVV and comparators was not standardized (e.g., not all pulses were recorded by the investigators; patients with suspected diagnosis of TAK rarely underwent investigation of the cranial arteries; temporal artery biopsy was not performed in all patients with suspected GCA). However, this limitation reflects the existing differences in how these diseases are assessed in routine clinical practice. Most patients were recruited from Europe, Asia, and North America, with fewer patients from Africa and Oceania. The performance characteristics of the criteria should be further tested in populations that were underrepresented in the DCVAS cohort and may have different clinical presentations of TAK. These criteria were developed using data collected from adult patients with vasculitis and should be tested in children with TAK (15).

The 2022 ACR/EULAR classification criteria for TAK are the product of a rigorous methodologic process that utilized an extensive data set generated by the work of a remarkable international group of collaborators. These criteria have been endorsed by the ACR and EULAR and are now ready for use in research.

ACKNOWLEDGMENTS

Guidelines and recommendations developed and/or endorsed by the American College of Rheumatology (ACR) are intended to provide guidance for patterns of practice and not to dictate the care of a particular patient. The ACR considers adherence to the recommendations within this guideline to be voluntary, with the ultimate determination regarding their application to be made by the clinician in light of each patient's individual circumstances. Guidelines and recommendations are intended to promote beneficial or desirable outcomes but cannot guarantee any specific outcome. Guidelines and recommendations developed and endorsed by the ACR are subject to periodic revision as warranted by the evolution of medical knowledge, technology, and practice. ACR recommendations are not intended to dictate payment or insurance decisions, and drug formularies or other third-party analyses that cite ACR guidelines should state this. These recommendations cannot adequately convey all uncertainties and nuances of patient care.

The ACR is an independent, professional, medical and scientific society that does not guarantee, warrant, or endorse any commercial product or service.

Objective. To provide evidence-based recommendations on the use of vaccinations in children and adults with rheumatic and musculoskeletal diseases (RMDs).

Methods. This guideline follows American College of Rheumatology (ACR) policy guiding management of conflicts of interest and disclosures and the ACR guideline development process, which includes the Grading of Recommendations Assessment, Development and Evaluation (GRADE) methodology. It also adheres to the Appraisal of Guidelines for Research and Evaluation (AGREE) criteria. A core leadership team consisting of adult and pediatric rheumatologists and a guideline methodologist drafted clinical population, intervention, comparator, outcomes (PICO) questions. A review team performed a systematic literature review for the PICO questions, graded the quality of evidence, and produced an evidence report. An expert Voting Panel reviewed the evidence and formulated recommendations. The panel

included adult and pediatric rheumatology providers, infectious diseases specialists, and patient representatives. Consensus required ≥70% agreement on both the direction and strength of each recommendation.

Results. This guideline includes expanded indications for some vaccines in patients with RMDs, as well as guidance on whether to hold immunosuppressive medications or delay vaccination to maximize vaccine immunogenicity and efficacy. Safe approaches to the use of live attenuated vaccines in patients taking immunosuppressive medications are also addressed. Most recommendations are conditional and had low quality of supporting evidence.

Conclusion. Application of these recommendations should consider patients' individual risk for vaccine-preventable illness and for disease flares, particularly if immunosuppressive medications are held for vaccination. Shared decision-making with patients is encouraged in clinical settings.

INTRODUCTION

Rheumatic and musculoskeletal diseases (RMDs) (1,2) and immunosuppressive medications used to treat them place patients at higher risk of vaccine-preventable infections and of more serious complications of infection. Vaccines have long been used to reduce illness from common viral and bacterial pathogens, and standardized vaccine schedules for children and adults have been widely adopted for use in both healthy people and those with chronic medical conditions (3,4). However, the immunogenicity and safety of vaccines may differ in patients with RMDs compared to the general population, and patients with RMDs may benefit from modified vaccine indications and/or adjustments to vaccination or medication schedules. Issues related to vaccination and medication management at the time of vaccination apply across diseases, and thus, this guideline is meant to help in the management of vaccines for all children and adults with RMDs in the US. The target audience is limited to rheumatology providers in the US because the epidemiology of vaccine-preventable infections and the availability of specific vaccines vary across the globe. However, providers in other countries may also find the guideline useful. A list of specific medications, vaccinations, and RMDs addressed in this guideline is found in Table 1, and a glossary of terms commonly used in this guideline can be found in Table 2.

Avacopan and bimekizumab, the pneumococcal vaccines PCV15 and PCV20, and the smallpox/monkeypox vaccine were not included in the formal evidence review because they were not approved at the time of the project plan. Antipyretic medications such as nonsteroidal antiinflammatory drugs and acetaminophen were also not included. Although a few randomized controlled trials (RCTs) have demonstrated blunted antibody responses with antipyretics, this was seen after primary vaccination only, and not after booster (5) or influenza vaccination (6). Observational studies also suggest that they have minimal-to-no impact on antibody responses to vaccination (5,7). Vaccinations against COVID-19 are not included in this guideline because, given the fast-changing nature of the pandemic and the COVID-19–related literature, there was concern that recommendations would be obsolete well before guideline publication. COVID-19 vaccinations will be incorporated into a future guideline update once the pertinent literature has stabilized. We refer readers to the American College of Rheumatology (ACR) COVID-19 vaccine guidance (8) and to the Centers for Disease Control and Prevention (CDC) website (9) for information on COVID-19 vaccines for patients with compromised immunity. Finally, we refer readers to the Advisory Committee on Immunization Practices (ACIP) (10) and the American Academy of Pediatrics (AAP) (11) vaccination guidelines for any other topics not addressed herein. This study did not involve human subjects, and therefore, approval from Human Studies Committees was not required.

The 2022 ACR guideline for vaccination in adults and children with RMDs highlights the following: 1) pneumococcal vaccination should be administered to all RMD patients taking immunosuppressive medication; 2) recombinant zoster vaccination is recommended for RMD patients >18 years of age taking immunosuppressive medication; 3) methotrexate should be held

Table 2. Glossary of terms

Term	Definition
Adjuvant	An ingredient used in some vaccines that helps create a stronger immune response in patients receiving the vaccine
Immunogenicity	The ability of a vaccine to elicit an immune response
Reactogenicity	Typical symptoms (e.g., fever, sore arm, muscle aches) that occur shortly (days) after vaccine administration either at the site of vaccination or systemically
Seroconversion	Development of antibodies to a pathogen, elicited by a vaccine (or infection), in the blood of an individual who previously did not have detectable antibodies
Seroprotection	An antibody level capable of protecting against infection or disease
Titer	Numerical value indicating the level of antibody against a particular pathogen

dose; and 6) infants exposed to tumor necrosis factor inhibitors (TNFi) in utero should receive rotavirus vaccination in the first 6 months of life.

METHODS

This guideline follows ACR policy guiding management of conflicts of interest and disclosures (https://www.rheumatology.org/Practice-Quality/Clinical-Support/Clinical-Practice-Guidelines) and the ACR guideline development process, which includes Grading of Recommendations Assessment, Development and Evaluation (GRADE) methodology (12,13), and adheres to the Appraisal of Guidelines for Research and Evaluation (AGREE) criteria (14). Supplementary Appendix 1, available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.25045, includes a detailed description of the methods. Briefly, the guideline team drafted clinical population, intervention, comparator, outcomes (PICO) questions (see Supplementary Appendix 2, available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.25045). The literature review team performed a systematic literature review for the PICO questions, graded the quality of evidence (high, moderate, low, very low), and produced the evidence report (see Supplementary Appendix 3, available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.25045). An expert Voting Panel reviewed the evidence report and then formulated and voted on recommendations. Additionally, a virtual Patient Panel reviewed the evidence and provided patient perspectives and preferences for consideration by the Voting Panel. The Patient Panel consisted of 9 patients with a variety of adult and pediatric RMDs and was moderated by a member of the core team (EC).

Voting Panel consensus required ≥70% agreement on both the direction (for or against) and strength (strong or conditional) of each recommendation, as per ACR practice. According to GRADE, a recommendation is categorized as strong if the panel is very confident that the benefits of an intervention clearly outweigh the harms (or vice versa); a conditional recommendation denotes uncertainty regarding the balance of benefits and harms, such as when the evidence quality is low or very low, or when costs are expected to impact the decision. Thus, for conditional recommendations, incorporation of patient preferences is particularly essential, acknowledging that patient preferences are an important part of all clinical decision-making. Rosters of the Core Leadership Team, Literature Review Team, Voting Panel, and Patient Panel are included in Supplementary Appendix 4, available on the *Arthritis Care & Research* website at http://onlinelibrary.wiley.com/doi/10.1002/acr.25045.

The following guiding principles were used in this guideline: 1) indicated vaccinations should be given to patients whenever possible; 2) this guideline is complementary to recommendations from the ACIP (10) and the AAP (15); 3) the decision to hold a medication before or after vaccination should consider the patient's disease, disease activity, and risk for vaccine-preventable infection; and 4) shared decision-making with patients is a key component of any vaccination strategy.

RESULTS/RECOMMENDATIONS

Expanded indications for specific vaccines in patients with RMDs receiving immunosuppression

Influenza vaccination

For patients with RMD age ≥65 years and patients with RMD age >18 years and <65 years who are taking immunosuppressive medication, giving high-dose or adjuvanted influenza vaccination is conditionally recommended over giving regular-dose influenza vaccination.

Any influenza vaccine is preferred over no influenza vaccine, and vaccination "today" is preferred over delay. Therefore, if high-dose or adjuvanted influenza vaccine is not available in the clinic during a patient visit when influenza vaccination is indicated, then standard-dose influenza vaccine should be administered. This caveat also applies in instances when insurance restrictions may preclude administration of high-dose or adjuvanted influenza vaccination to patients <65 years of age.

High-dose influenza vaccine is a quadrivalent vaccine containing 4 times the antigen as the standard-dose vaccine. Two RCTs in rheumatoid arthritis (RA) patients showed higher seroconversion rates in younger patients receiving high-dose vaccination compared to standard-dose vaccination with no safety signal (16,17). The adjuvanted influenza vaccine is a standard-dose quadrivalent vaccine containing the MF59 adjuvant, which elicits a strong antigenic response without the need for a higher antigen dose. No studies of the adjuvanted influenza vaccination in RMD patients age <65 years were identified in the literature search, but there

21514658, 2023, 0, Downloaded from https://onlinelibrary.wiley.com. By Wiley Online Library - on January 04, 2023. Re-use and distribution is strictly not permitted, except for Open Access articles

have been no safety issues seen with adjuvants in general, although they may be associated with greater reactogenicity (18).

Pneumococcal vaccination

For patients with RMD age <65 years who are taking immunosuppressive medication, pneumococcal vaccination is strongly recommended.

Patients with RMDs taking immunosuppressive medication may be at increased risk of pneumococcal infection (19,20). Multiple observational studies have evaluated the prime boost method of pneumococcal vaccination, with a pneumococcal conjugate vaccine (PCV13 or PCV15), followed 2 months later by a dose of the pneumococcal polysaccharide vaccine (PPSV23). A single-dose PCV20 vaccine is now approved in the US (21) and is likely to supplant this 2-dose strategy in the not-too-distant future, at least in adults. PCV15 and PCV20 polysaccharide conjugates are not currently approved for use in children in the US; but this too may soon change. The CDC currently recommends PCV15 followed by PPSV23 one year later, or PCV20, for adults <65 years taking immunosuppressive medications who were not previously vaccinated against pneumococcus, however, we recommend reference to CDC guidelines when choosing a specific pneumococcal vaccination strategy because this area is rapidly changing (21).

There are few studies evaluating the impact of disease-modifying antirheumatic drugs (DMARDs) on conjugate pneumococcal vaccines. The ACIP recommends administering pneumococcal vaccination to individuals age >18 years with certain chronic medical conditions and those taking immunosuppressive medication (10,22). The CDC and AAP recommend the primary PCV13 series to all children <2 years of age and PPSV23 vaccination to children age ≥2 years with underlying medical conditions (15).

Recombinant varicella-zoster virus (VZV) vaccination

For patients with RMD age >18 years who are taking immunosuppressive medication, administering the recombinant VZV vaccine is strongly recommended.

Patients with RMDs such as systemic lupus erythematosus (SLE) and RA are at higher risk of herpes zoster than older adults recommended for vaccination (23). Although the literature search identified no publications that specifically addressed recombinant VZV vaccination in patients with RMDs who are <50 years of age, this vaccine has been shown to be safe and effective in immunosuppressed patients undergoing renal transplantation (24) and autologous stem cell transplantation (25) and in patients with hematologic malignancies, many of whom are <50 years of age (26,27). The ACIP recommends recombinant VZV vaccination for individuals >18 years and <50 years of age who are immunocompromised and for the general public age ≥50 years (10). One retrospective study demonstrated mild disease flares in some patients around the time of vaccination (28), and reactogenicity is common with this vaccine (26).

Human papillomavirus (HPV) vaccination

For patients with RMD age >26 years and <45 years who are taking immunosuppressive medication and not previously vaccinated, vaccination against HPV is conditionally recommended.

Patients taking immunosuppressive medication may be at increased risk of cervical dysplasia and cervical cancer (29–33). Two studies of young patients with SLE (mean age 38 years and 26 years in the 2 studies, respectively) demonstrated that vaccination against HPV was immunogenic and well tolerated (34,35). The ACIP recommends HPV vaccination for individuals ages 11–26 years. For those ages 26–45 years who have not been previously vaccinated, ACIP recommends HPV vaccination based on shared decision-making (10). The benefits of vaccination after age 45 years diminish due to the greater likelihood of previous exposure to HPV.

Whether to hold immunosuppressive medication at the time of non–live attenuated vaccination to maximize vaccine immunogenicity, although holding medications could be associated with disease flare (Table 3).

Methotrexate

For patients with RMD, *holding* methotrexate for 2 weeks after influenza vaccination is conditionally recommended, assuming disease activity allows.

For patients with RMD, continuing immunosuppressive medications other than methotrexate around the time of influenza vaccination is conditionally recommended.

For patients with RMD, continuing immunosuppressive medications around the time of other (non-influenza) non–live attenuated vaccinations is conditionally recommended.

Many observational studies (36,37) suggest that methotrexate significantly blunts but does not completely abrogate the immunogenicity of influenza vaccination. Two RCTs demonstrated a beneficial impact of holding methotrexate around the time of influenza vaccination on vaccine immunogenicity (38,39). Assessment of flare risk and shared decision-making with the patient is recommended when deciding whether methotrexate should be held. Non-rheumatology providers (e.g., general pediatricians and internists) are encouraged to give influenza vaccination even if they are unsure as to whether to hold methotrexate, and then to consult with the patient's rheumatologist, rather than miss a vaccination opportunity. The literature review did not identify any studies that addressed holding medications in the context of vaccines other than for influenza. However, 2 studies published after completion of the literature review suggested that

Table 3. Medication management at the time of non–live attenuated vaccine administration

	Influenza vaccination	Other non–live attenuated vaccinations
Methotrexate	Hold methotrexate for 2 weeks *after* vaccination*	Continue methotrexate
Rituximab	Continue rituximab†	Time vaccination for when the next rituximab dose is due, and then hold rituximab for at least 2 weeks after vaccination
Immunosuppressive medications other than methotrexate and rituximab	Continue immunosuppressive medication	Continue immunosuppressive medication

□ = Conditional recommendation.
* Hold only if disease activity allows. Non-rheumatology providers, e.g., general pediatricians and internists, are encouraged to give the influenza vaccination and then consult with the patient's rheumatology provider about holding methotrexate to avoid a missed vaccination opportunity.
† Give influenza vaccination on schedule. Delay any subsequent rituximab dosing for at least 2 weeks after influenza vaccination if disease activity allows.

holding methotrexate at the time of COVID-19 vaccination is associated with greater vaccine immunogenicity (40,41).

The literature review identified no studies that directly addressed the impact of holding medications other than methotrexate at the time of influenza vaccination. Two RCTs performed in patients initiating TNFi versus placebo demonstrated similar responses to influenza vaccination in the 2 arms (42,43). Data on other biologic DMARDs and their relationship to influenza vaccine responses are much more limited (44–47).

Rituximab

For patients with RMD receiving rituximab, administering influenza vaccination on schedule is conditionally recommended rather than deferring vaccination until the next rituximab administration is due.

For patients with RMD receiving rituximab, *deferring* non–live attenuated vaccinations, other than influenza vaccination, until the next rituximab administration is due, and *delaying* rituximab for 2 weeks after vaccination, is conditionally recommended.

Influenza vaccine responses are greater when the vaccine is administered later rather than earlier after rituximab (48–50). Rituximab has also been shown to blunt responses to pneumococcal polysaccharide PPSV23 vaccination (51,52). Because of the seasonal nature of influenza, influenza vaccination is conditionally recommended to be given on schedule to patients receiving rituximab. For other non–live attenuated vaccinations, deferring vaccination until the next rituximab dose will improve vaccine immunogenicity. However, patients could also be vaccinated in the interest of acquiring some immunity and then revaccinated later (influenza vaccination could also be repeated using this same rationale). Whenever possible, vaccinations should be administered prior to rituximab initiation. Rituximab should be delayed for at least 2 weeks after any vaccination to allow time for the patient to develop an immune response, assuming that disease activity allows.

Whether to administer non–live attenuated vaccinations to patients receiving glucocorticoids or with active disease (Table 4).

Glucocorticoids

Whether to administer non–live attenuated vaccinations to patients taking glucocorticoids or defer vaccination to a later time point to maximize vaccine immunogenicity.

For patients with RMD who are taking the equivalent of prednisone ≤10 mg daily, administering any non–live vaccinations is strongly recommended.

For patients with RMD who are taking the equivalent of prednisone >10 mg daily but <20 mg daily, administering any non–live attenuated vaccinations is conditionally recommended.

For patients with RMD taking the equivalent of prednisone ≥20 mg daily, administering influenza vaccination is conditionally recommended.

For patients with RMD who are taking the equivalent of prednisone ≥20 mg daily, *deferring* non–live attenuated vaccinations, other than influenza vaccination, until glucocorticoids are tapered to the equivalent of prednisone <20 mg daily is conditionally recommended.

Most studies that have compared prednisone <10 mg daily to prednisone ≥10 mg daily found that the higher dosages did reduce influenza vaccine immunogenicity (53–55). Several studies that defined high-dose glucocorticoids as prednisone ≥20 mg daily observed that they blunted patients' vaccine response (56–58). Two studies that examined glucocorticoid dosage as a continuous variable identified a dose–response relationship while suggesting against a specific dose threshold (57,58). Evidence for the impact of glucocorticoids on responses to other vaccines is less consistent (59–61). For some vaccines, humoral responses can be measured and revaccination considered in those with an inadequate response.

Given the importance of timely influenza vaccination, a conditional recommendation was made to administer influenza vaccination to patients receiving the equivalent of prednisone ≥20 mg daily. For vaccines other than for influenza, a conditional

Prednisone ≥20 mg daily*	Give	Defer†

■ = Strong recommendation.
□ = Conditional recommendation.
* Or the equivalent dose of any other glucocorticoid formulation, or the equivalent pediatric dose.
† Defer vaccination until glucocorticoids are tapered to the equivalent of prednisone <20 mg daily.

recommendation was made to delay vaccination until the dose is lower to maximize vaccine efficacy. It is understood, however, that some patients may not be able to delay, e.g., children who require vaccination for school entry.

Disease activity

Whether to defer vaccination in patients with high disease activity to maximize vaccine immunogenicity and/or avoid worsening disease activity.

For patients with RMD, giving non–live attenuated vaccinations is conditionally recommended regardless of patients' disease activity.

Patients with RMD often express concern about whether vaccination can induce a disease flare, but the vast majority of studies failed to show any increased rate of flare after influenza vaccination. The results were similar for other vaccinations, although the quality of the evidence was low. Strong concerns, however, were expressed among the Patient Panel about the potential for vaccines to cause a disease flare, and shared decision-making is particularly important in this setting. Most studies suggest that increased disease activity does not impact vaccine immunogenicity (53,62), although one study did show lower seroconversion rates in pediatric lupus patients with a Systemic Lupus Erythematosus Disease Activity Index score of >8 who were vaccinated against influenza (57).

Managing immunosuppressive therapy at the time of live attenuated vaccination to avoid vaccine-associated illness (Table 5).

For patients with RMD who are taking immunosuppressive medication, *deferring* live attenuated vaccines is conditionally recommended.

For patients with RMD, *holding* immunosuppressive medication for an appropriate period before and 4 weeks after live attenuated virus vaccination is conditionally recommended.

For some live attenuated virus vaccines, such as for oral polio, oral typhoid, and influenza, there are inactivated alternatives that can be safely given to RMD patients taking immunosuppressive medication.

Conventional DMARDs. Two observational studies in patients with RMDs who were only taking conventional DMARDs and/or prednisone <20 mg daily at the time they received the yellow fever vaccine observed no cases of infection (63,64). Similarly, in a retrospective cohort study of patients with juvenile idiopathic arthritis (JIA) taking methotrexate and vaccinated against measles, mumps, and rubella (MMR), none developed vaccine-associated disease (65). Some pediatric rheumatologists do recommend giving live attenuated virus vaccine boosters (66) to children receiving low-dose immunosuppression when the child is likely to be taking the medication long term and when the risk of flare when not receiving immunosuppression is high, especially in areas with low community vaccination rates and/or during outbreaks (67). The AAP Red Book (15) and the Infectious Diseases Society of America (68) define low-level immunosuppression as methotrexate ≤0.4 mg/kg/week, azathioprine ≤3 mg/kg/day, prednisone <20 mg/day (or <2 mg/kg/day for patients weighing <10 kg), or alternate-day glucocorticoid therapy (68).

Biologic DMARDs. In a large RCT of RMD patients taking TNFi who were given the live attenuated VZV vaccine, there were no confirmed cases of varicella infection in either the vaccine or placebo group during 1 year of follow-up (69). Similarly, in an observational study of patients with Kawasaki disease who received vaccines against rotavirus and/or MMR plus varicella within 90 days prior to a single dose of infliximab, none experienced any serious infections (70). Finally, in a study of RA patients given a yellow fever booster 1 month after their last dose of infliximab, none developed symptoms of yellow fever (71).

In contrast, in a very small retrospective study based on an email survey to pediatric and adult rheumatologists and immunologists that reported on 17 children with autoinflammatory disorders or systemic JIA taking interleukin-1 or interleukin-6 receptor inhibitors and who were given a variety of live attenuated vaccinations, 3 of 17 patients developed vaccine-associated infection, and 7 of 17 patients experienced disease flares (72).

JAK inhibitors. Cutaneous vaccine-strain varicella infection developed in 1 of 55 RA patients given a single dose of the live attenuated VZV vaccine 2–3 weeks prior to tofacitinib initiation in the context of an RCT. Later testing demonstrated that the study participant lacked prevaccination immunity to VZV (73). Complete lack of immunity to varicella is rare in adults in the US, where the prevalence of varicella seropositivity is 98% in adults (74).

Intravenous immunoglobulin (IVIG). Antiviral antibodies contained in IVIG can interfere with replication of live attenuated vaccines and reduce their efficacy (75). The CDC recommends a delay of 8–11 months (depending on IVIG dose) between receipt of high-dose IVIG and live attenuated virus vaccination (76). However, there will be situations, such as during a measles outbreak,

Table 5. Immunosuppressive medication management at the time of live attenuated virus vaccine administration*

	Hold before live attenuated virus vaccine administration	Hold after live attenuated virus vaccine administration

Rituximab	6 months	4 weeks
IVIG#		
300–400 mg/kg	8 months	4 weeks
1 gm/kg	10 months	4 weeks
2 gm/kg	11 months	4 weeks

* TNF = tumor necrosis factor; IL = interleukin; BLyS = B lymphocyte stimulator; IVIG = intravenous immunoglobulin.
† For patients taking the equivalent of prednisone <20 mg/day or <2 mg/kg/day for patients weighing <10 kg or alternate-day glucocorticoid therapy (i.e., "low-level immunosuppression" [15,68]), these low doses can be continued if vaccination is critical and the risk of a disease flare or adrenal insufficiency when the patient is not taking glucocorticoids is high.
‡ For patients taking methotrexate ≤0.4 mg/kg/week or azathioprine ≤3 mg/kg/day ("low-level immunosuppression" [15,68]), hold times can be shortened if vaccination is critical and the risk of a disease flare when the patient is not taking immunosuppression is high.
§ For medications with >1 dosing interval approved by the Food and Drug Administration, the longest interval should be chosen (e.g., hold subcutaneous adalimumab for 2 weeks, although it can be dosed every 1 or every 2 weeks).
¶ In children with autoinflammatory disorders or systemic juvenile idiopathic arthritis in whom the risk of disease flare if biologic disease-modifying antirheumatic drugs are held is very high, shorter hold times can be considered if live attenuated vaccination is critical.
# The recommendation to hold IVIG prior to vaccination is designed to enhance vaccine efficacy, not safety. In some situations, such as during a measles outbreak, earlier vaccination would be preferred over delay.

when earlier vaccination is preferred over delay because some immunity will be preferred over none in that setting.

Specific recommendations for holding medications if live attenuated vaccines are given. Although the evidence around the safety of conventional DMARDs and TNFi at the time of live attenuated virus vaccination is reassuring, the total number of RMD patients who have been studied is small, and the Voting Panel conditionally recommended against administering live attenuated virus vaccines to patients receiving those agents as well as other forms of immunosuppression. For patients who do need to receive live attenuated vaccines, specific recommendations for holding immunosuppressive medications around the time of vaccination can be found in Table 5.

For slow-acting conventional DMARDs, a prevaccination hold time of 4 weeks was chosen to reflect their prolonged duration of action. However, direct evidence for the optimal hold time is lacking. For most biologic DMARDs, a hold time of 1 dosing interval before live attenuated vaccine administration is recommended.

The number of RMD patients who are taking immunosuppressive medications at the time that they need live attenuated virus vaccines is small. However, very young children, especially those with autoinflammatory disorders, may require biologic DMARDs before their primary vaccination series is complete. In these children, the risk associated with a disease flare may be considerably higher than the risk associated with the vaccine preventable illness (72). Children with autoinflammatory disorders also often require lifelong anticytokine therapy, and there may never be an opportunity to catch up on missed vaccinations later. For these children, shorter medication hold times can be considered if live attenuated virus vaccination is critical and cannot be delayed. Shared decision-making with the child's parents/guardians is important in this setting, and they should be alerted to the signs and symptoms of attenuated vaccine-associated infection.

The recommendation to hold immunosuppressive medications for 4 weeks after live attenuated vaccination is conservative. Typically, the duration of viremia (live virus circulating in the blood) after live attenuated vaccination is 2 weeks, although it can be longer in some patients (77). Viremia is more prolonged after primary vaccination than after booster vaccinations (77). Medication hold times after vaccination can be shortened if vaccination is critical and the risk of a disease flare when the patient is not receiving immunosuppression is high.

Close contacts of immunosuppressed patients should receive all age-appropriate vaccination (with the exception of smallpox) to avoid the vaccine-preventable diseases, as recommended by the ACIP (78). The ACIP also notes that no specific precautions are needed except if a household contact develops a rash after varicella vaccination, in which case direct contact should be avoided until the rash resolves (78). They also reinforce the recommendation to household members to wash their hands after diaper changing when an infant has received a rotavirus vaccine (78).

When to administer rotavirus vaccine to infants with second- and/or third-trimester antenatal exposure to biologic DMARDs in utero (Table 6).

For neonates/infants with second- and/or third-trimester antenatal exposure to TNFi, giving live attenuated rotavirus vaccine within the first 6 months of life is conditionally recommended.

For neonates/infants with second- and/or third-trimester antenatal exposure to rituximab, *delaying* live attenuated rotavirus vaccine until >6 months of age is conditionally recommended.

Vaccination against rotavirus typically occurs at 2 and 4 months, or at 2, 4, and 6 months. Rotavirus is rare in the US because of widespread immunization, and for this reason, the AAP recommends delaying rotavirus vaccination for 12 months after any in utero exposure to biologic DMARDs (except for certolizumab, which does not cross the placenta) (15). Three observational studies encompassing 58 children exposed to biologic DMARDs (most taking TNFi) who received live rotavirus vaccines reported no clear adverse events (79–81). Only minimal amounts of infliximab have been detected in the breast milk of treated patients (82).

The literature review identified no data on the effect of in utero rituximab exposure on later vaccine responses. Rituximab is a chimeric IgG1 molecule that can cross the placenta, and it has been associated with low or absent B lymphocyte levels in newborns who were exposed during the second or third (but not the first) trimester (83). Most reports demonstrate B cell recovery in these infants within 6 months after birth (83). Extrapolating from vaccine responses in adults treated with rituximab (48–50), infants exposed to rituximab are unlikely to respond to vaccination until 6 months postexposure. Although delayed rotavirus vaccine administration has been associated with an increased risk of intussusception, this complication remains quite rare (84).

After giving birth, most RMD patients turn to their general pediatrician rather than to their adult rheumatology provider for infant vaccination recommendations, and pediatricians may not be aware of the impact of in utero medication exposure on vaccine safety and immunogenicity. Therefore, recommendations regarding infant rotavirus vaccination after in utero exposure to either TNFi or rituximab should be discussed with the pregnant RMD patient prior to delivery. Specifically, the pregnant patient should be educated as to the fact that medications that cross the placenta may affect vaccination schedules for their infants. A copy of the current vaccine guideline summary (https://www.rheumatology.org/Portals/0/Files/Vaccinations-Guidance-Summary.pdf) may serve as a useful resource for the pregnant RMD patient to share with their pediatrician in advance of delivery.

Table 6. When to administer live attenuated rotavirus vaccination to infants exposed to immunosuppressive medications in utero*

Antenatal drug exposure in second or third trimester	Within the first 6 months of life	After 6 months of life
TNFi	Give rotavirus vaccine	–
Rituximab	Do not give rotavirus vaccine	Give rotavirus vaccine

□ = Conditional recommendation.
* TNFi = tumor necrosis factor inhibitor.

Whether to give multiple vaccinations to patients with RMD on the same day.

For patients with RMD, giving multiple vaccinations on the same day rather than giving each individual vaccination on a different day is conditionally recommended.

Administering >1 vaccination on a single day is a routine practice in both pediatric and adult medicine that is supported by the CDC in order to avoid a missed vaccination opportunity (85). Patient representatives on the Voting Panel felt that shared decision-making was important in this instance due to their concerns about the potential for reactogenicity or disease flare.

A summary of the guideline recommendations, associated PICO questions, and level of evidence can be found in Table 7.

DISCUSSION

This is the first guideline to address vaccination strategies across the entire adult and pediatric RMD spectrum. An underlying principle in this guideline is that patients should be vaccinated, and that missed vaccination opportunities should be avoided or minimized. This is particularly true regarding influenza vaccination, which is administered seasonally and is recommended for RMD patients even if their disease activity is high, they are taking high-dose glucocorticoids, and/or are taking rituximab. The Voting Panel generally favored simple recommendations to encourage vaccination and foster guideline adherence. There are few studies assessing the immunogenicity and safety of specific vaccines in relation to specific immunosuppressive medications, and there are virtually no studies assessing the impact of holding medications around the time of vaccination, particularly for vaccines other than for influenza. Therefore, many of the recommendations are conditional and apply across diseases, vaccines, medications, and age groups. Because of the low quality of the evidence, shared decision-making between clinicians and patients/parents/guardians is particularly important for the vaccination strategies presented here. These recommendations do not supersede clinical judgement.

Most recommendations in this guideline are aimed at maximizing vaccine immunogenicity because the literature revealed few vaccine safety signals, at least regarding non-live vaccinations. Many vaccines are required for school entry to protect not only the health of the individual but also that of the broader community. Public health requirements may supersede some recommendations made here. Insurance barriers could inhibit implementation of these recommendations, such as to administer high dose or adjuvanted influenza vaccine or recombinant VZV to RMD patients <65 years of age taking immunosuppressive medications. In such instances, this guideline could be used as a resource to aid in prior authorization.

Not included in this guideline are recommendations for COVID-19 vaccination in patients with RMD. Readers can refer to the CDC for the most up-to-date recommendations for COVID-19 vaccination, including for patients taking immunosuppressive

Table 7. Summary of recommendations*

Recommendations	Level of evidence†	PICO	Evidence table page numbers
Expanded indications for specific vaccines in patients with RMDs receiving immunosuppression			
Influenza vaccination			
For patients with RMD age ≥65 years and patients with RMD age >18 and <65 years who are taking immunosuppressive medication, giving high-dose or adjuvanted influenza vaccination is **conditionally** recommended over giving regular-dose influenza vaccination.	PICO 9. Very low (indirect evidence only)‡	PICO 9. In patients with RMD age ≥65 years, is high-dose influenza vaccine more effective than seasonal regular-dose influenza vaccine?	728
	PICO 10. Very low (indirect evidence only)‡	PICO 10. In patients with RMD age ≥65 years, is adjuvanted influenza vaccine more effective than seasonal regular-dose influenza vaccine?	728
	PICO 11. Moderate	PICO 11. In patients with RMD <65 years of age, is high- dose vaccine more effective than seasonal regular-dose influenza vaccine?	728–737
	PICO 12. Very low (indirect evidence only)‡	PICO 12. In patients with RMD <65 years of age, is adjuvanted influenza vaccine more effective than seasonal regular-dose influenza vaccine?	737
Pneumococcal vaccination			
For patients with RMD age <65 years who are taking immunosuppressive medication, pneumococcal vaccination is **strongly** recommended.	PICO 20. Low	PICO 20. Should patients with RMD receive vaccination against pneumococcus at age <65 years?	933–952
Recombinant VZV vaccination			
For patients with RMD age >18 years who are taking immunosuppressive medication, administering the recombinant VZV vaccine is **strongly** recommended.	PICO 21. Very low (indirect evidence only)‡	PICO 21. Should patients with RMD receive VZV vaccination at age <50 years?	952
HPV vaccination			
For patients with RMD age >26 and <45 years who are taking immunosuppressive medication and are not previously vaccinated, vaccination against HPV is **conditionally** recommended.	PICO 19. Very low	PICO 19. Should patients with RMD be vaccinated against HPV at age >26 years?	931–933
Whether to hold immunosuppressive medication at the time of non–live attenuated vaccination to maximize vaccine immunogenicity, although holding medications could be associated with disease flare			
For patients with RMD, *holding* methotrexate for 2 weeks after influenza vaccination is **conditionally** recommended, assuming disease activity allows.	PICO 3. Very low for most comparisons, moderate for a few	PICO 3. In patients with [RMD disease X], what is the effect of [drug Y/drug class] on immunization responses to [vaccine Z, vaccine type] in comparison with [general population, or drug Y]?	7–550
	PICO 15. TNFi: low; tocilizumab: very low; secukinumab: very low; tofacitinib: moderate; glucocorticoids: very low; abatacept: very low	PICO 15. In patients with RMD, does the immunogenicity or efficacy of influenza vaccine differ in patients taking drug Y as compared to those not taking drug Y at the time of vaccination?	754–898
	PICO 16. MTX: moderate; tofacitinib: low; other medications: indirect evidence only	PICO 16. Should patients with RMD taking drug Y hold their drug Y for a period of time prior to or after receiving (not live attenuated) vaccines?	898–927

Table 7. (*Cont'd*)

Recommendations	Level of evidence†	PICO	Evidence table page numbers
For patients with RMD, giving multiple vaccinations on the same day rather than giving each individual vaccination on a different day is **conditionally** recommended.	PICO 22. Very low (indirect evidence only)‡	PICO 22. Should patients with RMD receive standardized regimens of vaccine combinations?	952

■ = Strong recommendation.
□ = Conditional recommendation.
* PICO = population, intervention, comparator, outcomes; RMD = rheumatic and musculoskeletal disease; VZV = varicella-zoster virus; HPV = human papillomavirus; MTX = methotrexate; TNFi = tumor necrosis factor inhibitors; DMARDs = disease-modifying antirheumatic drugs.
† The terms 'moderate', 'low', and 'very low' are based on the Grading of Recommendations Assessment, Development and Evaluation (GRADE) definitions for quality of evidence. Moderate quality means that "further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate." Low quality means that "further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate." Very low quality means that "we are very uncertain about the estimate." In the systematic review for this guideline, a judgment of moderate quality required at least some evidence from randomized controlled trials, and a judgment of low quality required at least some evidence from well-designed observational studies with appropriate comparator groups.
‡ Indirect evidence indicates that there is evidence from other populations with RMD or other health conditions, or evidence that does not fully address the comparison specified in a PICO question.

medication (9). Recommendations about holding immunosuppressive medications at the time of non–live attenuated virus vaccination in this guideline (Table 3) differ from those recommended around the time of COVID-19 vaccination in the ACR COVID-19 vaccine guidance (8). This is because prior to the introduction of COVID-19 vaccines in late 2020, there was little population-level immunity to the SARS–CoV-2 virus, and maximizing vaccine efficacy was a public health imperative. In contrast, when considering routine vaccinations, the desire to avoid an RMD flare weighs more heavily in the balance. Therefore, there are very few instances where this guideline recommends holding medication at the time of non–live attenuated virus vaccination. Studies that demonstrate diminished vaccine responses in RMD patients receiving immunosuppression (other than rituximab) generally demonstrate diminished, but not completely abrogated, responses.

Finally, the literature review demonstrated that much more evidence is needed to guide practice in this area. Knowledge gaps where further research is needed are as follows: 1) standardization of trial design and outcome measures to test the efficacy and durability of response to all vaccines across all age groups; 2) safety of primary and booster live attenuated virus vaccination in children taking methotrexate and/or biologic DMARDs; 3) assessment of the immunogenicity, reactogenicity, and disease flares following standard-dose, high-dose, and adjuvanted influenza vaccination, recombinant VZV vaccination, and primary and booster COVID-19 vaccination in RMD patients taking immunosuppressive medication; and 4) RCTs to test the safety and efficacy of holding DMARDs around the time of vaccination.

ACKNOWLEDGMENTS

We thank the patients who (along with authors Ida Hakkarinen and Grayson Schultz) participated in the Patient Panel meeting: Jacob Anderson, Rachelle Crow-Hercher, Kathy Full, Sandra Nye, Mary Turner, Shilpa Venkatachalam, and Bene Williams. We thank the ACR staff, including Regina Parker, for assistance in coordinating the administrative aspects of the project, Cindy Force, for assistance with manuscript preparation, and Amy Turner, for overall supervision of the project. We thank Janet Waters for her assistance in developing the literature search strategy, as well as performing the initial literature search and update searches. We thank Susan Goodman, MD, for her help shepherding the project.

AUTHOR CONTRIBUTIONS

All authors were involved in drafting the article or revising it critically for important intellectual content, and all authors approved the final version to be submitted for publication. Dr. Bass had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Study conception and design. Bass, Chakravarty, Akl, Bingham, Calabrese, Cappelli, Imundo, Winthrop, Baden, Curtis, Smith, Fontanarosa, Lakin, Sadun, Tam, Turner, Reston.

Acquisition of data. Chakravarty, Calabrese, Imundo, Baden, Bridges, Schultz, Calabrese, Cunha, Fontanarosa, Gillispie-Taylor, Gkrouzman, Iyer, Lakin, Legge, Lo, Lockwood, Sadun, Singh, Sullivan, Tam, Turgunbaev, Reston.

Analysis and interpretation of data. Bass, Chakravarty, Akl, Bingham, Calabrese, Cappelli, Johnson, Winthrop, Arasaratnam, Baden, Berard, Bridges, Cheah, Curtis, Ferguson, Hakkarinen, Onel, Schultz, Sivaraman, Smith, Sparks, Vogel, Williams, Calabrese, Fontanarosa, Gillispie-Taylor, Gkrouzman, Legge, Lockwood, Singh, Sullivan, Tam, Turgunbaev, Reston.

2022 American College of Rheumatology (ACR) Guideline for Vaccinations in Patients with Rheumatic and Musculoskeletal Diseases

Guideline Summary

Objective: To provide evidence-based recommendations on the use of vaccinations in children and adults with rheumatic and musculoskeletal diseases (RMDs).

Methods: This guideline follows the ACR guideline development process and ACR policy guiding management of conflicts of interest and disclosures, which includes the Grading of Recommendations, Assessment, Development and Evaluations (GRADE) methodology, and adheres to the Appraisal of Guidelines for REsearch & Evaluation (AGREE) criteria. A core leadership team consisting of adult and pediatric rheumatologists drafted clinical population, intervention, comparator, and outcomes (PICO) questions. A literature review team performed a systematic literature review for the PICO questions, graded the quality of evidence, and produced the evidence report. The evidence was reviewed, and recommendations were formulated by an expert Voting Panel that included adult and pediatric rheumatology providers, infectious diseases specialists, and patient representatives. Consensus required ≥70% agreement on both the direction and strength of each recommendation.

Results: This guideline includes expanded indications for some vaccines in patients with RMDs, as well as guidance on whether to hold immunosuppressive medications or delay vaccination to maximize vaccine immunogenicity. Safe approaches to the use of live-attenuated vaccines in patients on immunosuppressive medications are also addressed. The overall quality of the evidence supporting the recommendations is low, and most recommendations are conditional.

Conclusion: Application of these recommendations should take into consideration patients' individual risk for vaccine-preventable illness and for disease flares, particularly if immunosuppressive medications are held for vaccination. Shared decision-making with patients is encouraged in clinical settings.

This summary was approved by the ACR Board of Directors on July 11, 2022. These recommendations are included in a full manuscript, which will be submitted for publication in Arthritis & Rheumatology and Arthritis Care and Research.

Expanded indications for specific vaccines in patients with RMDs on immunosuppression

For RMD patients aged ≥ 65 years, and RMD patients aged >18 and <65 years who are on immunosuppressive medication, giving high-dose or adjuvanted influenza vaccination is conditionally recommended over giving regular-dose influenza vaccination.

For patients with RMD aged <65 years who are on immunosuppressive medication, pneumococcal vaccination is strongly recommended.

For patients with RMD aged >18 years who are on immunosuppressive medication, administering the recombinant zoster vaccine is strongly recommended.

For patients with RMD aged >26 and <45 years who are on immunosuppressive medication and not previously vaccinated, vaccination against HPV is conditionally recommended.

Whether to give multiple vaccinations to RMD patients on the same day

For RMD patients, giving multiple vaccinations on the same day rather than giving each individual vaccination on a different day is conditionally recommended.

Medication management at the time of non-live attenuated vaccine administration

	Influenza vaccination	Other non-live attenuated vaccinations
Methotrexate	Hold methotrexate for 2 weeks *after* vaccination*	Continue methotrexate
Rituximab	Continue rituximab**	Time vaccination for when the next rituximab dose is due, and then hold rituximab for at least 2 weeks after vaccination
Immunosuppressive medications other than methotrexate and rituximab	Continue immunosuppressive medication	Continue immunosuppressive medication

*Hold only if disease activity allows. Non-rheumatology providers, e.g., general pediatricians and internists, are encouraged to give the influenza vaccination and then consult with the patient's rheumatology provider about holding methotrexate to avoid a missed vaccination opportunity.

**Give influenza vaccination on schedule. Delay any subsequent rituximab dosing for at least 2 weeks after influenza vaccination if disease activity allows.

= Conditional recommendation

Whether to give or defer non-live attenuated vaccinations in patients taking glucocorticoids, regardless of disease activity

	Influenza vaccination	Other non-live attenuated vaccinations
Prednisone ≤ 10 mg daily*	Give	Give
Prednisone > 10 mg and < 20 mg*	Give	Give
Prednisone ≥ 20 mg daily*	Give	Defer**

*Or the equivalent dose of any other glucocorticoid formulation, or the equivalent pediatric dose

**Defer vaccination until glucocorticoids are tapered to the equivalent of prednisone < 20 mg daily

= Strong recommendation

= Conditional recommendation

For patients with RMD, giving non-live attenuated vaccinations is conditionally recommended regardless of their disease activity.

Immunosuppressive medication management at the time of live-attenuated virus vaccine administration

For RMD patients who are on immunosuppressive medication, deferring live-attenuated vaccines is conditionally recommended.

For RMD patients, holding immunosuppressive medication for an appropriate period before (see Table below) and 4 weeks after live-attenuated virus vaccination is conditionally recommended.

Immunosuppressive medication	Hold before live-attenuated virus vaccine administration	Hold after live-attenuated virus vaccine administration
Glucocorticoids[a]	4 weeks	4 weeks
Methotrexate, azathioprine[b]	4 weeks	4 weeks
Leflunomide, mycophenolate mofetil, calcineurin inhibitors, oral cyclophosphamide	4 weeks	4 weeks
JAK inhibitors	1 week	4 weeks
TNF, IL17, IL12/23, IL23, BAFF/BLyS inhibitors	1 dosing interval[c]	4 weeks
IL6 pathway inhibitors	1 dosing interval[d]	4 weeks
IL1 inhibitors		
Anakinra	1 dosing interval[d]	4 weeks
Rilonacept	1 dosing interval[d]	4 weeks
Canakinumab	1 dosing interval[d]	4 weeks
Abatacept	1 dosing interval[c]	4 weeks
Anifrolumab	1 dosing interval[c]	4 weeks
Cyclophosphamide IV	1 dosing interval[c]	4 weeks
Rituximab	6 months	4 weeks
IVIG [e]		
300-400 mg/kg	8 months	4 weeks
1 gm/kg	10 months	4 weeks
2 gm/kg	11 months	4 weeks

JAK= Janus kinase; TNF=tumor necrosis factor; IL=interleukin; IVIG= intravenous immunoglobulin G; IV = intravenous

[a] for patients taking the equivalent of prednisone < 20 mg/day or < 2 mg/kg/day for patients weighing < 10 kg, or alternate-day glucocorticoid therapy (i.e., "low level immunosuppression" (14, 68), these low doses can be continued if vaccination is critical and the risk of a disease flare or adrenal insufficiency off glucocorticoids is high.

[b] for patients taking methotrexate ≤ 0.4 mg/kg/week or azathioprine ≤ 3 mg/kg/day ("low level" immunosuppression" (14, 68), hold times can be shortened if vaccination is critical and the risk of a disease flare off immunosuppression is high.

[c] for medications with more than one FDA-approved dosing interval, the longest interval should be chosen (e.g., hold subcutaneous adalimumab for 2 weeks although it can be dosed every 1 or every 2 weeks).

[d] In children with autoinflammatory disorders or systemic juvenile idiopathic arthritis in whom the risk of disease flare if biologic DMARDs are held is very high, shorter hold times can be considered if live-attenuated vaccination is critical.

[e] the recommendation to hold IVIG prior to vaccination is designed to enhance vaccine efficacy, not safety. In some situations, such as during a measles outbreak, earlier vaccination would be preferred over delay.

When to administer live-attenuated rotavirus vaccination to infants exposed to immunosuppressive medications in utero

Antenatal drug exposure in second or third trimester	Within the first 6 months of life	After 6 months of life
TNF inhibitor	Give rotavirus vaccine	
Rituximab	Do not give rotavirus vaccine	Give rotavirus vaccine

Yvonne Truepenny[35], Kishore Warrier[36], Mark Yates [9], Charalampia Papadopoulou[20], Neil Martin[37,38], Liza McCann[39,†] and Hector Chinoy [1,2,4,†], for the British Society for Rheumatology Standards, Audit and Guidelines Working Group

Key words: myositis, muscle, adolescent rheumatology, paediatric/juvenile rheumatology, DMARDs, immunosuppressants

Scope and purpose

Background

Idiopathic inflammatory myopathy (IIM) is a multi-system autoimmune condition characterised by muscle inflammation (myositis), interstitial lung disease (ILD), and skin manifestations with an incidence of up to 19 per 1,000,000 person-years in adults and up to 4 per 1,000,000 person-years in children. Estimated UK prevalence (for adult-onset IIM) is 10, 000 [1, 2].

Need for guideline

No rigorously produced evidence-based guidelines for IIM spanning juvenile and adult-onset disease exists. Assimilating key research relating to management and formation of practical evidence-based recommendations will aid clinicians and help optimize management and outcomes.

Target audience

The target readership is clinicians caring for patients with IIM, including paediatric and adult rheumatologists, neurologists, dermatologists, respiratory physicians, oncologists, gastroenterologists, and cardiologists. Rheumatology and neurology nurses, physiotherapists, occupational therapists, podiatrists, speech and language therapists, specialist rheumatology pharmacists, and psychologists will also find these recommendations relevant.

Areas the guideline does not cover

Diagnosis, classification, and investigation of suspected IIM are not addressed. Inclusion body myositis is not covered.

Stakeholder involvement

The project was led by an executive committee (J.B.L., A.G.S.O., H.C., N.M., L.M.). A multidisciplinary working group was convened with input from rheumatologists (D.I., H.G., H.T., N.Mc., A.P., P.G., S.T., H.C., P.K., P.M.M., A.G.S.O.), paediatric rheumatologists (C.Pi., C.Pa., N.Ma., K.W., L.M., T.A.), neurologists (J.B.L., M.H.), a paediatric neurologist (S.Sp.), a nurse (P.L.), a pharmacist (O.A.), a dermatologist (S.M.), paediatric dermatologist (R.M.), physiotherapists (V.C., S.M., W.J.G.), and a former GP/Specialty Doctor in Rheumatology (J.J.). Lay (patient and relative) input was also received throughout the process (P.T., Y.T., J.S., P.R.). The guideline production process was informed by a EULAR Recommended Methodologist (P.M.M.) and literature searches were carried out by experts at the Centre for Rheumatic Diseases, Kings College London (J.G., K.B., M.Y.).

Rigour of development

This guideline was developed in line with the BSR Creating Clinical Guidelines Protocol using AGREEII (Appraisal of Guidelines for Research and Evaluation II) methodology.

Selection of key questions

Starting March 2018, the executive committee and working group agreed the guideline scope and created key questions structured using the PICO (patient or population, intervention, comparison, outcome) format. Each question was subdivided into focused clinical questions during the evidence review and recommendation formulation process.

Literature search—scope and search strategy

Using key questions as a basis, a literature search was undertaken using Ovid (see 'Search terms' in Supplementary Material S1, available at *Rheumatology* online). Search results and additional manually identified references up to October 2020 were included. Evidence published after October 2020 was not included as this was the cut-off for eligibility. A potential limitation of this guideline is that relevant literature may have been published since October 2020; data or information from these studies could not be included in the recommendation formation process.

Eligibility criteria

Published peer reviewed clinical studies relating to any IIM subtype except inclusion body myositis were included. Case reports/series were limited to those describing outcomes for three or more subjects. Review articles, editorials, conference proceedings, and existing clinical guidelines were excluded. Non-English language papers were excluded unless a translation was published. Basic science studies without clear clinical applicability were excluded. Abstracts of papers were reviewed by

Downloaded from https://academic.oup.com/rheumatology/article/61/5/1760/6555980 by guest on 03 February 2023

two authors to determine eligibility against these criteria (PRISMA flow diagram shown in Supplementary Fig. S1, available at *Rheumatology* online).

Methods used to formulate recommendations

The full text of each eligible paper was reviewed by two assessors using Grading of Recommendations, Assessment, Development, and Evaluations (GRADE) methodology. Each reference was categorized as high (A), moderate (B) or low/very low (C) quality. A third assessor resolved disagreements.

A total of 213 papers were used to form recommendations. See Supplementary Table S1 (available at *Rheumatology* online) for details of evidence base contributing to recommendations.

Draft recommendations were created and categorized as applicable to all patients, adult-specific or paediatric-specific. The process outlined by the Scottish Intercollegiate Guidelines Network (SIGN) [3] was used to summarize the quality of body of evidence for each recommendation: high (A), moderate (B), low (C) or very low (D), according to GRADE methodology.

Content, wording, strength of recommendation (strong = 1, conditional = 2), and quality of supporting evidence for each recommendation were subjected to a formal consensus building process using a combination of face-to-face meetings and online surveys. Strength of agreement (SoA) for finalized recommendations was determined using a simple binary voting system for each voter and is presented as a percentage. Authors were free to abstain from voting on areas where they did not feel clinically competent, with the percentage reflecting voters. Only recommendations with a SoA >80% were included in the guideline.

Policy for updates

Requirement for updates will be considered by the BSR Standards, Audit, and Guidelines Working Group and according to principles outlined in the BSR Creating Clinical Guidelines Protocol.

Recommendations

Recommendations are followed by parentheses detailing GRADE and SoA details (strength of recommendation, quality of body of evidence, SoA).

(i) How should skeletal muscle inflammation (myositis) be treated?

1-High dose glucocorticoids should be used to treat active muscle inflammation at time of treatment induction (1, B, 100%).

1a-Adult-specific. Oral prednisolone at a dose of 0.5–1 mg/kg/day, usually 40–60 mg, is recommended (1, B, 100%).

1b-Paediatric-specific. Oral prednisolone at a dose of 1–2 mg/kg/day or intravenous methylprednisolone pulses 30 mg/kg/day, maximum 1 g daily i.v. dose is recommended (1, B, 100%).

1c-Intravenous methylprednisolone is to be considered, especially when there are concerns about gastrointestinal absorption. Use of intravenous methylprednisolone may allow increased therapeutic effect and less toxicity compared with oral glucocorticoid (2, B, 96%).

2-Oral prednisolone should be tapered according to clinical response (1, B, 100%).

3-Disease modifying anti-rheumatic drugs should be used to reduce muscle inflammation, achieve clinical remission and reduce steroid burden (1, C, 100%).

3a-Paediatric-specific. Early, complete control of muscle weakness and inflammation should be sought in juvenile-onset IIM, with the aim of improving outcomes and reducing disease-related complications (1, B, 100%).

3b-Paediatric-specific. A combination of high dose glucocorticoid and methotrexate should be used as first-line treatment in most cases (1, B, 100%).

3c-Paediatric-specific. A combination of prednisolone and methotrexate, as opposed to prednisolone and ciclosporin, should be used for the treatment of juvenile-onset IIM as this has a more favourable side effect profile (1, B, 100%).

3d-Paediatric-specific. Mycophenolate mofetil is to be considered as a treatment option to improve skin and muscle disease (2, C, 100%).

3e-Adult-specific. Methotrexate, azathioprine, tacrolimus, ciclosporin, and mycophenolate mofetil are to be considered for the treatment of active myositis and long-term maintenance of disease remission (2, C, 96%).

4-Intravenous immunoglobulin should be considered as a treatment of severe and/or refractory muscle inflammation (1, B, 100%).

5-Management of IIM should include a safe and appropriate exercise programme led and monitored by a specialist physiotherapist and/or a specialist occupational therapist to improve quality of life and function (1, B, 100%).

6-Rituximab is to be considered as a treatment option for refractory myositis and may be particularly effective in (2, A, 100%):

a. Juvenile-onset disease
b. Patients with a positive myositis autoantibody profile
c. Patients with lower burden of disease damage

7-Cyclophosphamide should be considered as a treatment option for severe and/or refractory IIM (1, B, 100%).

8-Adult-specific. Abatacept is to be considered as a treatment option in refractory adult IIM (2, B, 100%).

Glucocorticoids are crucial for myositis remission induction and maintenance. Glucocorticoid dose should be weaned when disease activity, considered across all domains, substantially improves, usually after around 6 weeks of treatment initiation. Available evidence precludes evidence-based recommendations regarding rate of glucocorticoid dose reduction. Whilst dosages per kilogram are included in recommendations for juvenile onset disease, it is important to note that ceiling doses may apply. Steroid-free remission can be facilitated

Downloaded from https://academic.oup.com/rheumatology/article/61/5/1760/6555980 by guest on 03 February 2023

using DMARDs and/or additional immunosuppressive/immunomodulatory treatments. Evidence exists to support use of conventional synthetic DMARDs (csDMARDs) (tacrolimus, azathioprine, methotrexate, ciclosporin, mycophenolate mofetil) alongside glucocorticoids early in the disease course to induce and maintain remission, although conflicting results exist in some cases [4–10]. Evidence does not exist to allow recommendation of specific csDMARDs as first-/second-/third-line for adults. DMARDs should be prescribed and monitored according to existing age-appropriate BSR guidelines [11, 12].

Exercise is safe and effective for people with IIM and can improve quality of life and function. Specialist physiotherapy and occupational therapy input is important for management of patients with IIM and should be considered in service planning to ensure appropriate access for all patients.

Evidence exists allowing recommendation of use of 'second-line' treatments, such as CYC, rituximab (RTX), IVIG and abatacept, for patients with persistent active disease despite glucocorticoid and csDMARD therapy. A prospective, double-blind, randomized, placebo-controlled phase III study, completed after the cut-off date for evidence inclusion, has demonstrated efficacy of IVIG [13].

CYC is an option for severe and/or refractory IIM. Route of administration should be considered since intravenous (i.v.) CYC (intermittent pulses), compared with oral CYC, is associated with fewer side effects. CYC is usually administered by i.v. infusion [14], reducing risk of leucopenia, haemorrhagic cystitis, and gonadal toxicity [15, 16].

RTX and IVIG are options for management of active IIM (e.g. myositis, dysphagia, refractory skin disease) refractory to glucocorticoid/csDMARD-based immunosuppression. In England, RTX and IVIG can only be used according to NHS England (NHSE) commissioning stipulations and should be prescribed in conjunction with a specialist centre [17, 18]. NHSE guidance does not apply in Wales, Northern Ireland or Scotland. In Scotland, the National Plasma Products Expert Advisory Group (NPPEAG) indicates IVIG as appropriate for patients with resistant or aggressive disease [19]. A single prospective delayed-start study has demonstrated the benefit of abatacept in adult-onset IIM [20]. Future studies are required to confirm efficacy.

At time of recommendation consensus forming there was insufficient evidence to recommend anti-TNF-α therapy for treatment of myositis. There was also insufficient evidence to recommend use of Janus kinase (JAK) inhibitors in IIM treatment; however, published case series are promising and future clinical trials may provide a stronger evidence base [21–23].

(ii) How should IIM-related skin manifestations be treated?

1-Rituximab is to be considered for the treatment of skin disease refractory to glucocorticoid/csDMARD-based immunosuppression (2, B, 100%).

2-IVIG should be considered for the treatment of skin disease refractory to glucocorticoid/csDMARD-based immunosuppression (1, B, 100%).

3-Sun avoidance and regular use of high factor broad spectrum sun cream is to be considered to reduce likelihood of a disease flare affecting skin or muscle (2, C, 100%).

4-**Paediatric-specific**. Systemic immunosuppressive drugs are to be considered for the treatment of ongoing skin disease activity, including reduced nailfold capillary density (2, C, 100%).

5-**Paediatric-specific**. An early increase in treatment is to be considered in patients with persistent skin disease to aid remission and reduce development of calcinosis (2, C, 100%).

Inadequate evidence exists to allow recommendation of topical agents to treat IIM-specific skin manifestations; however, topical tacrolimus and glucocorticoids could be considered alongside dermatology input.

Evidence relating to treatment of IIM-related skin manifestations is limited; however, studies indicate the ability of both IVIG and RTX to treat skin manifestations refractory to glucocorticoid/csDMARD-based immunosuppression. Nailfold capillary abnormalities in children with IIM can reflect systemic disease activity and should be considered when making treatment decisions [24].

Studies indicate sun exposure is associated with cutaneous and non-cutaneous DM and JDM disease flares [25]. Sun avoidance may thus form part of the management strategy for DM/JDM.

(iii) How should IIM-related ILD be managed?

1-**Paediatric-specific**. Routine assessment of pulmonary function, including measurement of diffusing capacity or transfer factor of the lung for carbon monoxide (DLCO or TLCO) in juvenile-onset IIM should be performed, as pulmonary function abnormalities are frequent and may be asymptomatic (1, B, 100%).

2-**Adult-specific**. Interstitial lung disease should be screened for in high-risk patients (1, B, 100%).

3-**Adult-specific**. In the treatment of rapidly progressive interstitial lung disease (RP-ILD):

a. Induction therapy with high dose steroids is to be considered (2, C, 96%).
b. The use of ciclosporin or tacrolimus, alongside steroids, is to be considered in patients with RP-ILD (2, C, 96%).
c. Cyclophosphamide or rituximab therapy is to be considered early, potentially as part of the induction regimen (2, C, 96%).

4-**Adult-specific**. In the treatment of chronic IIM-associated interstitial lung disease:

a. Immunosuppression using steroids with or without a single DMARD (azathioprine, ciclosporin, tacrolimus, mycophenolate) is to be considered (2, C, 100%).
b. Rituximab or cyclophosphamide is to be considered in treatment-resistant patients (2, C, 100%).

Downloaded from https://academic.oup.com/rheumatology/article/61/5/1760/6555980 by guest on 03 February 2023

IIM-related ILD management should be carried out alongside ILD-specialist respiratory physicians. ILD risk is increased with anti-synthetase syndrome, presence of an anti-synthetase-associated autoantibody, anti-melanoma differentiation-associated protein 5 autoantibody positivity, and scleroderma overlap. ILD screening methods include plain chest X-ray radiography, pulmonary function tests (including DLCO), and where indicated, high resolution CT scanning. Insufficient evidence exists to advise ILD screening frequency.

Insufficient evidence exists to form recommendations regarding pharmacological management of IIM-associated ILD in paediatric patients.

(iv) What management steps should be taken to reduce fracture risk in people with IIM?

1-Adult-specific. A bone health assessment should be performed, regardless of glucocorticoid therapy, and appropriate management instigated (1, B, 100%).

Fracture risk consideration in IIM is important given glucocorticoid use, female preponderance, and average age of onset for adult disease [26]. Fragility fracture risk assessment should be carried out in accordance with NICE guidance at time of diagnosis and whenever risk factors change [27]. Glucocorticoid weaning, once remission is attained, may reduce fragility fracture risk.

Studies, although limited by small populations, suggest JDM is associated with increased vertebral fracture risk, even before substantial corticosteroid exposure [28].

(v) What key prognostic and management factors should be considered for children with IIM?

1-Paediatric-specific. Juvenile-onset IIM should be managed by paediatric specialists as it differs from adult-onset IIM in several ways, including greater presence of subcutaneous calcification, less disease damage, lack of association with cancer, increased risk of vasculitis, and different autoantibody associations (1, C, 95%).

2-Paediatric-specific. Shorter time to diagnosis is associated with improved disease outcome, therefore early referral to a specialist service is to be considered (2, C, 100%).

3-Paediatric-specific. Age-specific considerations should be taken into account when using tools that measure muscle strength, function, and quality of life (1, B, 100%).

4-Paediatric-specific. Healthcare professionals should look for signs of connective tissue disease overlap, which is associated with increased risk of mortality (1, C, 89%).

5-Paediatric-specific. Patients with juvenile-onset IIM should be assessed for calcinosis (1, C, 100%).

Age appropriate tools such as the Childhood Myositis Assessment Score, Childhood Health Assessment Questionnaire, and Juvenile Dermatomyositis Multidimensional Assessment Report should be used to assess muscle strength, function, and quality of life [29, 30]. There is significantly higher mortality in patients with overlapping connective tissue disease features compared with those with JDM [31]. Patients should therefore be carefully screened for overlapping connective tissue disease features and wider organ involvement.

Factors associated with increased risk of calcinosis include younger age at disease onset, particularly disease onset in infancy, delay to diagnosis or delay to treatment initiation, more severe disease, prolonged disease duration, and presence of anti-nuclear matrix protein 2 (NXP2) autoantibodies [32, 33]. Clinical examination and plain X-ray radiography can be used to identify calcinosis.

(vi) Is autoantibody testing useful in people with IIM?

1-Patients should be tested for myositis auto-antibodies (1, B, 100%).

Myositis-specific antibodies and myositis-associated autoantibodies can facilitate diagnosis, inform disease phenotype and prognosis, and may help tailor treatment [34, 35]. Interpretation of immunoblot results should be carried out in the context of the patient's overall clinical presentation. Autoantibody titres should not be used to monitor disease activity.

(vii) How should cancer be screened for in people with an IIM?

1-Paediatric-specific. Routine screening for cancer is not warranted in juvenile-onset IIM (1, B, 100%).

2-Adult-specific. The risk of cancer should be considered in all patients and screening should be particularly considered in those with the following risk factors (1, B, 100%):

- Older age at onset
- Male gender
- Dysphagia
- Cutaneous necrosis
- Resistance to immunosuppressive therapy
- Rapid disease onset
- Positive anti-TIF1-γ autoantibodies
- Positive anti-NXP2 autoantibodies
- Negative for known myositis-specific autoantibodies

There is an association between adult-onset IIM and malignancy. Evidence pertaining to effective cancer screening is limited but indicates the utility of CT scanning of the thorax, abdomen, and pelvis for at-risk patients, such as anti-transcriptional intermediary factor-1γ (anti-TIF1-γ) positive patients. Tumour markers and ^{18}F-FDG PET/CT scanning can be considered in selected patients.

In contrast with adult-onset IIM, juvenile onset IIM is not associated with cancer, with literature consisting only of isolated case reports. Routine cancer screening in juvenile-onset IIM is not advised unless underlying cancer is suspected.

Downloaded from https://academic.oup.com/rheumatology/article/61/5/1760/6555980 by guest on 03 February 2023

(viii) How should IIM treatment during pregnancy and the breastfeeding period be amended?

1-Those wishing to conceive should be advised to plan conception whilst their disease is well controlled (1, B, 100%).

2-Pregnancy should be managed in conjunction with maternal medicine specialists (1, B, 96%).

3-Increased vigilance is required post-partum as patients may be at risk of disease flare (1, C, 96%).

Pregnancy should be managed alongside maternal medicine specialists due to lower mean birth weight, increased risk of obstetric complications, such as pre-eclampsia and eclampsia, and longer hospitalization duration during delivery. Evidence, although limited, indicates good IIM control is associated with better pregnancy outcomes [36]. Conception should be planned once disease remission is established using medications compatible with pregnancy according to the BSR guideline on prescribing drugs in pregnancy and breastfeeding [37].

(ix) How should IIM-related cardiovascular disease be assessed for and treated?

1-**Adult-specific**. Patients should undergo a regular cardiovascular risk assessment (1, C, 100%).

2-**Paediatric-specific**. Assessment and management of cardiovascular risk factors is to be considered, including hypertension, obesity or metabolic abnormalities (lipids/insulin resistance) (2, C, 100%).

IIM is associated with an increased incidence of hypertension, diabetes, dyslipidaemia, obesity, and coronary artery disease (adult-specific) representing an opportunity for intervention to reduce cardiovascular risk [38, 39]; however, insufficient evidence exists to advise screening frequency.

Micro-vasculopathy and glucocorticoid treatment are considered responsible for the hypertension observed in 25–50% of patients with JDM [40]. Studies have identified altered cardiovascular risk factors in JDM patients [41] that may lead to increased risk of early atherosclerosis later in adulthood [42].

(x) How should cardiac involvement in IIM be screened for?

1-**Adult-specific**. Patients should undergo screening for cardiac involvement; serum cardiac damage markers, ECG, echocardiography, and cardiac MRI are to be considered (2, B, 100%).

2-**Adult-specific**. Cardiac troponin I (not cardiac troponin T) should be used as the preferred serum marker for screening and monitoring cardiac involvement (1, B, 100%).

3-**Paediatric-specific**. Screening for cardiac involvement in patients with juvenile-onset IIM with ECG and echocardiogram is to be considered (2, C, 100%).

Cardiac myositis is associated with increased morbidity and mortality risk. Raised serum cardiac damage markers may indicate cardiac involvement. However, some 'cardiac-specific' markers, particularly cardiac troponin T, can also be expressed and released from regenerating skeletal muscle, potentially causing ambiguity. Measuring cardiac troponin I is recommended. Several cardiac abnormalities, including left ventricular dysfunction, ECG abnormalities, and reduced heart rate variability [43, 44], have been reported in people with IIM.

(xi) How should IIM-related dysphagia be screened for and managed?

1-Routine assessment of dysphagia is to be considered in all patients (2, C, 92%).

2-Swallowing assessment and involvement of speech and language therapist/gastroenterology teams is to be considered in those with dysphagia (2, C, 100%).

3-IVIG therapy for active disease and dysphagia resistant to other treatments is to be considered (2, C, 100%).

Dysphagia is common, impacts upon quality of life, and is associated with weight loss and aspiration pneumonia, which can be fatal. Swallowing dysfunction may not always be predicted by generalized muscle weakness [45]. Risk is increased with anti-NXP2 positivity or malignancy [46]. Clinicians should routinely enquire for dysphagia-related symptoms and consider early involvement of speech and language therapists when required.

Dysphagia is recognized as an indication for IVIG treatment by NHSE [18]. IVIG and other immunomodulatory therapies including glucocorticoid, csDMARDs (methotrexate, azathioprine, ciclosporin, tacrolimus, mycophenolate mofetil, hydroxychloroquine), CYC, and RTX have been reported to improve symptoms of dysphagia and/or objective swallow assessments.

(xii) How should quality of life and mental wellbeing be assessed and treated in people with IIM?

1-Psychological wellbeing and psychiatric comorbidities should be assessed (1, C, 92%).

2-Psychological wellbeing and health-related quality of life should be routinely assessed using an age-appropriate tool (1, B, 100%).

3-Factors negatively impacting upon health-related quality of life (e.g. skin involvement, pruritis, steroid adverse effects) should be addressed (1, C, 96%).

4-**Paediatric-specific**. Factors negatively impacting upon health-related quality of life in children include pain, muscle weakness, and poor sleep, and should be managed appropriately (1, C, 95%).

5-Individually tailored exercise and/or rehabilitation should be encouraged across all ranges of disease activity with the aim of improving psychological wellbeing (1, B, 96%).

6-Where relevant, targeted exercises given by a specialist physiotherapist and/or a specialist occupational

Downloaded from https://academic.oup.com/rheumatology/article/61/5/1760/6555980 by guest on 03 February 2023

therapist to improve grip strength should be considered, due to the negative impact of poor grip strength on activities of daily living and quality of life (2, C, 96%).

Significant deficits are evident in measures of health-related quality of life (HRQoL) in both adult and juvenile-onset IIM. Evidence suggests a number of IIM-specific factors that can negatively impact HRQoL, such as active disease, increased functional impairment, and decreased muscle strength [47]. HRQoL can be assessed using tools such as the Child Health Questionnaire (CHQ-50) and the 36-Item Short Form Survey (adult-specific) [48]. Minimizing functional impairment via specialist physiotherapy and/or occupational therapy should be considered. Screening for concerns such as low mood and anxiety, and offering psychological interventions as early possible where needed can be considered.

(xiii) What IIM management considerations should be made for certain ethnic groups?

1-Ethnicity is to be considered when assessing patients; clinical manifestations, associated autoantibodies, and underlying risk factors may vary according to ethnicity (2, C, 96%).

Ethnic minority groups appear to be at increased risk of anti-signal recognition particle (anti-SRP) autoantibody-related disease, increased cardiovascular risk, and more at risk of juvenile polymyositis/juvenile connective tissue myopathy. Calcinosis rates are higher in black children with JDM in North American [49] and South African cohorts [50].

Applicability and utility

Supplementary Fig. S2 (available at *Rheumatology* online) shows an overview of recommendations. There should be no barriers to implementation in the UK. Use of the audit tool (Supplementary Table S2, available at *Rheumatology* online) is encouraged.

This guideline highlights the limited high-quality evidence base available for IIM, with relative absence of RCTs or head-to-head comparison of treatments. Recommendations are therefore predominantly based on observational studies. Controlled trials are crucial to further evaluate promising treatments. Long-term outcomes especially related to cardiovascular or cerebrovascular risks needs better definition. Impact of IIM on mental health and quality of life should not be underestimated. Patients and carers should be fully integrated in defining priorities for future IIM research.

Acknowledgements

Myositis UK and JDCBS endorse the British Society for Rheumatology guideline on the management of paediatric, adolescent and adult patients with idiopathic inflammatory myopathy, which has followed NICE accredited processes in its development and production. The authors would like to thank BSR for support provided throughout each stage of formation of the guideline. The authors would also like to thank Myositis UK for funding provision that supported formation of the guideline. The authors would like to thank Dr Jennifer Hannah who took part in voting during the consensus meeting.

J.B.L., A.G.S.O., H.C., N.M. and L.M. led guideline formation throughout all stages. J.B.L., A.G.S.O., H.C., N.M., L.M. and C.Pa. prepared the guideline manuscript, which was reviewed and approved by all co-authors. J.G., K.B. and M.Y. led the systematic review process. P.T., Y.T., J.S. and P.R. provided lay (patient and relative) input throughout the process. All authors contributed to the consensus building and recommendation finalisation process and approved the final manuscript.

Funding: A.G.S.O. and H.C. are supported by the National Institute for Health Research Manchester Biomedical Research Centre Funding Scheme. The views expressed in this publication are those of the authors and not necessarily those of the National Health Service, the National Institute for Health Research, or the Department of Health. During production of these guidelines A.G.S.O. received salary support from Myositis UK and Versus Arthritis (Award Number: 21993); J.B.L. held an NIHR Clinical Lectureship in Neurology (NWN/006/025/A); P.L. was funded by a National Institute for Health Research (NIHR)/Health Education England (HEE) Clinical Doctoral Research Fellowship (ICA-CDRF-2016-02-032); S.L.T. held an NIHR Clinical Lectureship in Rheumatology (SEV/008/020A) funded by Royal United Hospitals NHS Foundation Trust and the Bath Institute for Rheumatic Diseases; and K.B. was funded by the Medical Research Council in the form of a Clinical Training Research Fellowship (CTRF MR/R001332/1). Support was also received from the British Society for Rheumatology to fund travel and other expenses associated with a face-to-face consensus building meeting.

Disclosure statement: All authors have made declarations of interest in line with BSR policy (see Supplementary Material, available at Rheumatology online). J.B.L. has received honoraria from Sanofi Genzyme, Biogen, and Roche. P.M.M. has received honoraria from Abbvie, BMS, Celgene, Eli Lilly, Galapagos, Janssen, MSD, Novartis, Orphazyme, Pfizer, Roche, and UCB. J.J. works in a unit that has received funding from Pfizer. H.C. works in a unit that has received funding from Eli Lilly, MedImmune, and Novartis; has received educational funding support from Corbus Pharmaceuticals; and has received honoraria from Argenx, Abbvie, AstraZeneca, Janssen, Orphazyme, UCB, Biogen, and Novartis. P.K. has received honoraria from Abbvie, Amgen, Eli Lilly, Gilead, Sanofi, and Sobi. W.J.G. has received educational funding support from UCB, and has received honoraria from Pfizer and Novartis. H.T. has received honoraria from Eli Lilly, Abbvie, Janssen, Novartis, Biogen, and UCB. All other authors have declared no conflicts of interest.

ABSTRACT

Objective The original European League Against Rheumatism recommendations for managing fibromyalgia assessed evidence up to 2005. The paucity of studies meant that most recommendations were 'expert opinion'.

Methods A multidisciplinary group from 12 countries assessed evidence with a focus on systematic reviews and meta-analyses concerned with pharmacological/non-pharmacological management for fibromyalgia. A review, in May 2015, identified eligible publications and key outcomes assessed were pain, fatigue, sleep and daily functioning. The Grading of Recommendations Assessment, Development and Evaluation system was used for making recommendations.

Results 2979 titles were identified: from these 275 full papers were selected for review and 107 reviews (and/or meta-analyses) evaluated as eligible. Based on meta-analyses, the only 'strong for' therapy-based recommendation in the guidelines was exercise. Based on expert opinion, a graduated approach, the following four main stages are suggested underpinned by shared decision-making with patients. Initial management should involve patient education and focus on non-pharmacological therapies. In case of non-response, further therapies (all of which were evaluated as 'weak for' based on meta-analyses) should be tailored to the specific needs of the individual and may involve psychological therapies (for mood disorders and unhelpful coping strategies), pharmacotherapy (for severe pain or sleep disturbance) and/or a multimodal rehabilitation programme (for severe disability).

Conclusions These recommendations are underpinned by high-quality reviews and meta-analyses. The size of effect for most treatments is relatively modest. We propose research priorities clarifying who will benefit from specific interventions, their effect in combination and organisation of healthcare systems to optimise outcome.

INTRODUCTION

Fibromyalgia is common with a prevalence of 2% in the general population.[1 2] However, its diagnosis and management remain a challenge for patients and healthcare professionals. It often takes >2 years for a diagnosis to be made with an average of 3.7 consultations with different physicians.[3] Referral to specialists and investigations results in high healthcare use, for up to 10 years prior to diagnosis, compared with persons who do not have fibromyalgia.[4] Although pain is the dominant symptom in fibromyalgia, other symptoms such as fatigue, non-refreshed sleep, mood disturbance and cognitive impairment are common, but not universal, have an important influence on quality of life and emphasise that it is a heterogeneous and complex condition.[5 6]

The original European League Against Rheumatism (EULAR) recommendations for the management of fibromyalgia assessed evidence up to and including 2005.[7] Given the paucity of information and poor quality of the studies available, it was recommended that the guidelines be revised after a period of 4 years. However, no subsequent revision took place and thus a decade later we revisit the recommendations with the aim of making them more evidence based. In the time since the original recommendations, there have been a considerable number of individual trials examining pharmacological and non-pharmacological interventions and, moreover, there have been systematic reviews conducted for nearly all of the commonly used management strategies. Our aim therefore was, using the systematic reviews conducted and taking into account their quality, to make evidence-based recommendations for the use of individual pharmacological and non-pharmacological approaches, and how these could be combined. Further, we aimed to identify priority areas for future research.

METHODS

Working group membership

The working group included 18 members from 12 European countries: clinicians (representing rheumatology, internal medicine, pain medicine and epidemiology), non-clinical scientists (occupational health, epidemiology), patient representatives and the allied health professions (nursing).

Eligibility, search strategy and quality assessment

We focused on systematic reviews (with or without meta-analysis) concerned with the management of fibromyalgia. Details of eligibility, review and quality assessment are provided in online supplementary text.

Evaluating evidence

We retained pain as one of the key outcomes of interest, from the original guidelines, but also included fatigue, sleep and daily functioning. The committee considered the following in making a

To cite: Macfarlane GJ, Kronisch C, Dean LE, *et al*. *Ann Rheum Dis* 2017;**76**:318–328.

Ann Rheum Dis: first published as 10.1136/annrheumdis-2016-209724 on 4 July 2016. Downloaded from http://ard.bmj.com/ on February 3, 2023 by guest. Protected by copyright.

recommendation: number of trials, number of patients, outcomes assessed, quality of reviews and the trials included within the reviews, effect size (and 95% CI), adverse events and cost. We used the Grading of Recommendations Assessment, Development and Evaluation system for making recommendations.[10] This is a four-point scale: strong for/weak for/weak against/strong against; or allowing a recommendation 'use only for research'. The strength of recommendation is based on the balance between desirable and undesirable effects (considering values and preferences), confidence in the magnitude of effects and resource use. A strong recommendation implies that, if presented with the evidence, all or almost all informed persons would make the recommendation for or against the therapy, while a weak recommendation would imply that most people would, although a substantial minority would not.[11]

Two subgroups considered the evidence for pharmacological and non-pharmacological therapies and proposed a recommendation. At a face-to-face meeting, after presentation of the evidence and the preliminary recommendation, discussion resulted in a 'final recommendation'. In addition to the evidence on efficacy/effectiveness, the committee also took into account safety. All participants then voted on their level of agreement with the recommendation on a scale from 0, 'completely disagree', to 10, 'completely agree'. The percentage of the committee scoring at least 7 was taken to indicate level of agreement.

RESULTS

In total, 2979 titles were identified. From these, 571 abstracts and then 275 full papers were selected for review, and 107 reviews evaluated as eligible for consideration in making recommendations for management (figure 1).

Information on the reviews informing these recommendations on pharmacological therapy and on non-pharmacological and complementary and alternative medicines/therapies is collated in online supplementary tables A and B, respectively, while information from one review, for each medicine/therapy, selected based on recency and quality is provided in tables 1 and 2, respectively.

Evaluation of pharmacological medicines

Amitriptyline

Five reviews included up to 13 trials and a maximum of 919 subjects. Häuser *et al*[12] reported that patients receiving amitriptyline were more likely to achieve 30% pain reduction (risk ratio (RR) 1.60, 95% CI 1.15 to 2.24), equivalent to a 'number needed to treat' (NNT) of 3.54, 95% CI 2.74 to 5.01. There was a moderate effect on sleep (standardised mean difference (SMD) −0.56, 95% CI −0.78, to −0.34)[i] and small effect on fatigue (−0.44; −0.71 to −0.16). There was no difference in discontinuation rates compared with patients receiving placebo. Nishishinya *et al*[13] in their high-quality review concluded that 25 mg/day improved pain, sleep and fatigue at 6–8 weeks of treatment but not at 12 weeks while 50 mg/day did not demonstrate efficacy. *Amitriptyline evaluation: weak for, at low dose (100% agreement).*

Anticonvulsants

Nine reviews of pregabalin included up to seven studies and a maximum of 3344 patients. A recent Cochrane review[24] reported patients receiving active treatment were more likely to have 30% pain reduction, RR 1.37, 95% CI 1.22 to 1.53, with a 'number needed to benefit' (NNTB) over placebo of 9, 95% CI 7 to 13. There was a very small effect on fatigue (−0.17; −0.25 to −0.09) and small effect on sleep (−0.35; −0.43 to −0.27) but no effect on disability (−0.01; −0.11 to 0.09). A single, moderate quality, study of gabapentin in 150 subjects (eg, in ref. 104) showed a significant effect on 30% pain reduction (RR 1.65, 95% CI 1.10 to 2.48), a small effect on sleep (−0.71; −1.08 to −0.24) and a large effect on disability (−0.94; −1.32 to −0.56). *Anticonvulsant evaluation: pregabalin—weak for (94% agreement); gabapentin—research only (100% agreement).*

Cyclobenzaprine

A single systematic review of five studies involving 312 patients reported that of those taking cyclobenzaprine 85% experienced side effects and only 71% completed the studies. They were more likely to report themselves as 'improved' (NNT 4.8, 95% CI 3.0 to 11.0). Only two studies reported an 'intention-to-treat' (ITT) analysis. Sleep, but not pain, showed a significant, very small, improvement relative to baseline at the longest outcome considered (12 weeks: SMD 0.34) and patients on placebo showed similar improvement (SMD 0.52).[25] *Cyclobenzaprine evaluation: weak for (75% agreement).*

Growth hormone

A single systematic review of two studies involving 74 patients reported an effect size on pain of 1.36 (0.01 to 1.34).[16] The improvement in functional deficit was not statistically significant (1.24; −0.36 to 2.84). There are concerns on safety (sleep apnoea, carpal tunnel syndrome). The drug is not approved for fibromyalgia (FM) or related disorders in Europe. *Growth hormone evaluation: strong against (94% agreement).*

Monoamine oxidase inhibitors

Four reviews identified up to three studies and 241 patients. Häuser *et al*[26] reported a moderate effect on pain across the studies (−0.54; −1.02, to −0.07), but the single studies that evaluated fatigue and sleep showed no effect. There were no differences in dropouts or adverse events compared with placebo. There was no comparison between compounds. Life-threatening interactions have been documented. *Monoamine oxidase inhibitors (MAOIs) evaluation: weak against (81% agreement).*

NSAIDs

A single review[21] identified two small trials with no evidence of improved outcome compared with placebo. One low-quality review was not considered. *Non-steroidal anti-inflammatory drugs (NSAIDs) evaluation: weak against (100% agreement).*

Serotonin-noradrenalin reuptake inhibitors

Eight systematic reviews were identified, which presented data separately for duloxetine. The largest review of 2249 subjects[32] reported duloxetine, short term (up to 12 weeks) and long term (up to 28 weeks), was more effective than placebo at reducing pain (RR >30% pain, RR 1.38, 95% CI 1.22 to 1.56), although there was no significant effect at 20–30 mg/day and no difference between doses of 60 and 120 mg/day. NNTB, based on 60 mg/day up to 12 weeks, was 6, 95% CI 3 to 12. A previous review reported small effects on sleep (−0.24; −0.37, to −0.12) and disability (−0.33; −0.43, to −0.24) but no effect on fatigue.[30] Seven systematic reviews were identified of milnacipran, a recent one of which evaluated five trials.[30] Patients taking milnacipran were more likely, at the end of treatment, to

[i]All effect sizes are expressed as SMD with 95% CI unless otherwise stated.

Ann Rheum Dis: first published as 10.1136/annrheumdis-2016-209724 on 4 July 2016. Downloaded from http://ard.bmj.com/ on February 3, 2023 by guest. Protected by copyright.

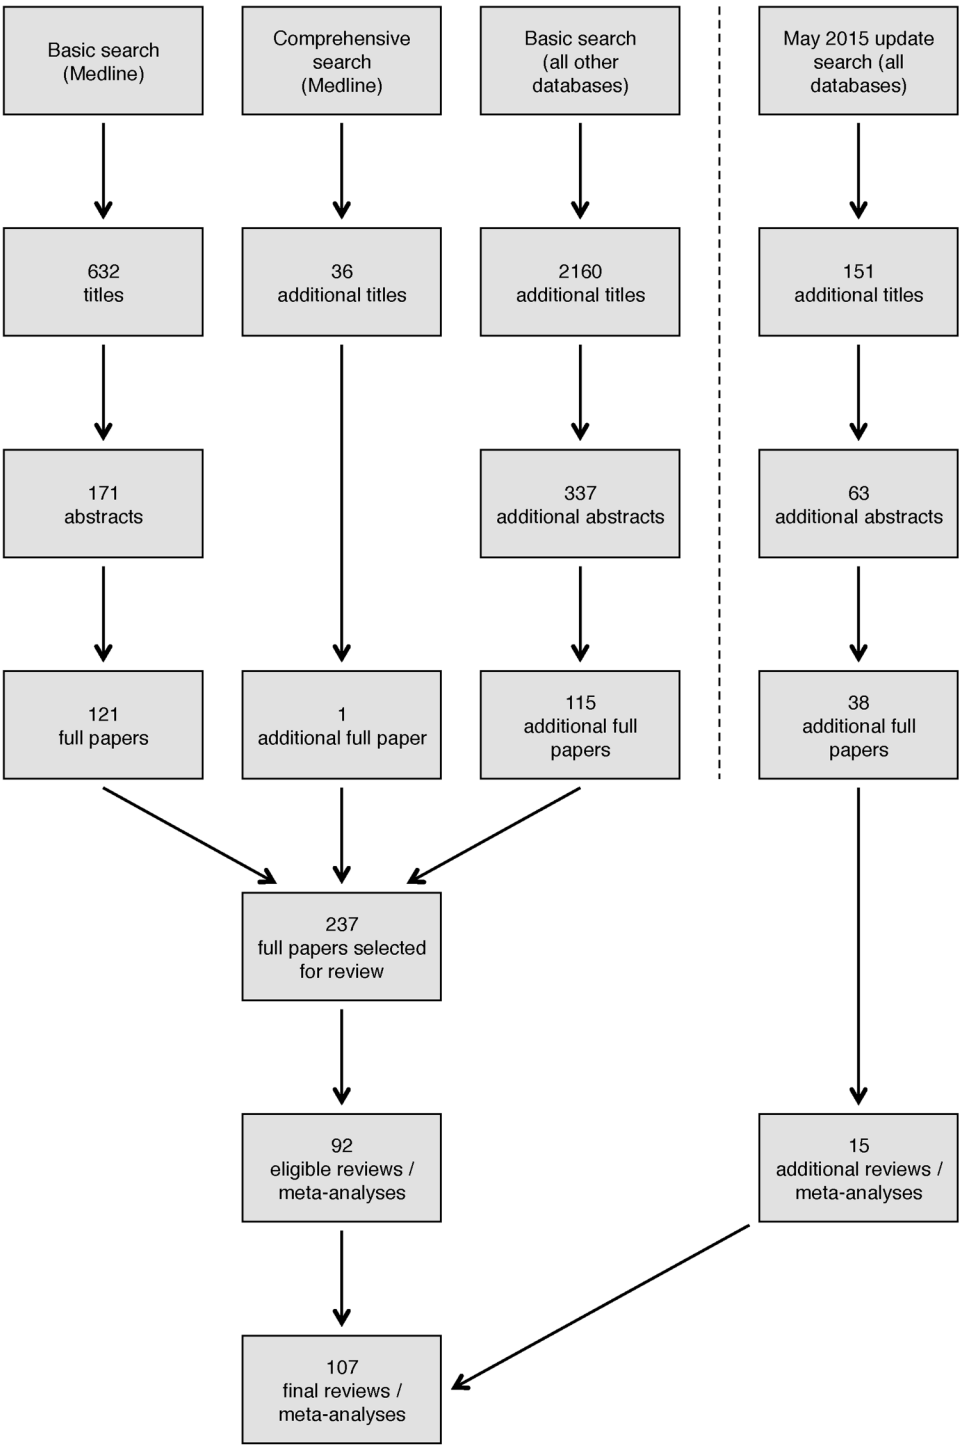

Figure 1 Flow chart identifying eligible reviews.

have 30% pain reduction (RR 1.38, 95% CI 1.25 to 1.51) but there was only a small benefit on fatigue (−0.14; −0.19 to −0.08), disability (−0.16; −0.23 to −0.10) and no effect on sleep. *Duloxetine and milnacipran evaluation: weak for (100% agreement).*

Selective serotonin reuptake inhibitors

Seven systematic reviews included up to 11 trials and a maximum of 521 subjects. Given that reviews have not focused on specific drugs or comparisons, drugs within this class were considered together. A recent review of medium quality included seven trials and reported a moderate effect on pain (−0.40; −0.73, to −0.07), sleep (−0.31; −0.60 to −0.02) and no effect on fatigue (−0.17; −0.46 to 0.11).[36] *Selective serotonin reuptake inhibitor (SSRI) evaluation: weak against (94% agreement).*

Sodium oxybate

A single systematic review of five studies including 1535 patients reported small effects sizes on pain (0.44; 0.31 to 0.58), sleep problems (0.47; 0.28 to 0.66) and fatigue (0.48; 0.35 to 0.60). The European Medicines Agency and the US Food and Drug Administration refused the approval for FM because of safety concerns.[16] The drug is only approved for narcolepsy. *Sodium oxybate evaluation: strong against (94% agreement).*

Ann Rheum Dis: first published as 10.1136/annrheumdis-2016-209724 on 4 July 2016. Downloaded from http://ard.bmj.com/ on February 3, 2023 by guest. Protected by copyright.

Table 1 Overview of results from selected systematic reviews of placebo-controlled pharmacological trials

Treatment (review reference)	No. of trials (no. of participants) Review quality	Dosages; durations of treatment	Overall trial quality*	Safety and comments
Amitriptyline[12]	10 (767) AMSTAR=6	10–50 mg/day; 8–24 weeks	Low	There was no analysis of safety but no difference in discontinuation rates compared with patients on placebo was reported.
Anticonvulsants—pregabalin[24]	5 (3256) AMSTAR=10	Three studies with fixed doses of 300, 450 and 600 mg/day; one with fixed doses of 150, 300 or 450 mg/day; one flexible dosing study of 300 or 450 mg/day; 8–14 weeks	High	Increased likelihood of withdrawal due to adverse events, RR 1.68, 95% CI 1.36 to 2.07; NNH 12 95% CI 9 to 17. No difference in likelihood of serious adverse events.
Cyclobenzaprine[25]	5 (312) AMSTAR=7	10–40 mg; 2–24 weeks	Moderate	There was no analysis of adverse outcomes in the trials reviewed although dropout across trials was large (cyclobenzaprine 29%, placebo 43%). Only two studies conducted ITT.
Growth hormone[16]	2 (74) AMSTAR=5	0.0125 mg/kg/day; adjusted to maintain IGF-1 level of 250 ng/mL after first month, 0.0125 mg/kg/day; 9 months to 1 year	NE	Safety concerns include sleep apnoea and carpal tunnel syndrome.
MAOIs[26]	3 (241) AMSTAR=9	Pirlindole 150 mg/day, moclobemide 150–300 mg/day; 4–12 weeks	Low	MAOIs are known to cause potentially fatal hypertensive crises, serotonin syndrome and psychosis when they interact with foods containing tyramine and medications (many of which are commonly used in the treatment of FM), including SSRIs, tricyclic antidepressants and tramadol. The clinical trials had restrictions on concomitant medications.
NSAIDs[21]	2 (242) AMSTAR=7	Ibuprofen 600 mg four times a day, tenoxicam 20 mg/day; 6–8 weeks	Low	The adverse event profile, although not considered in this review, is well established for this class of drugs.
SNRIs—duloxetine[31]	6 (2249) AMSTAR=10	20–120 mg/day; 12–28 weeks	Moderate	Dropout rates due to side effects across studies higher than with placebo. No difference in serious adverse events.
SNRIs—milnacipran[30]	5 (4118) AMSTAR=10	100 or 200 mg/day; 12–27 weeks	High	Dropout rates due to side effects across studies were double compared with placebo, but there was no difference in serious adverse events.
SSRIs[36]	7 (322) AMSTAR=8	20–40 mg/day citalopram, 20–80 mg/day fluoxetine, 20–60 mg/day paroxetine; 6–16 weeks	Moderate to high	Acceptability and tolerability were similar to placebo NNH 40, 95% CI 19 to 66. Although several studies excluded patients with depression/anxiety, Häuser *et al*[26] showed a small effect of SSRIs in improving depressed mood (SMD −0.37, 95% CI −0.66 to −0.07).
Sodium oxybate[16]	5 (1535) AMSTAR=5	4.5–6 g/day; 8–14 weeks	NE	There is the potential for abuse and central nervous system effects associated with abuse such as seizure, respiratory depression and decreased levels of consciousness.
Tramadol[22]	1 (313) AMSTAR=3	37.5 mg tramadol/325 mg paracetamol 4×/day; 3 months	High	No significant difference in discontinuation due to adverse events (RR 1.62, 95% CI 0.94 to 2.80). A high-quality review (AMSTAR score 7) identified a single study, which, among persons who tolerated and benefitted from tramadol, demonstrated a lower discontinuation rate in a double-blind phase compared with placebo.[21]

*According to the method of quality evaluation used in the review.
AMSTAR, Assessing the Methodological Quality of Systematic Reviews; FM, fibromyalgia; IGF, insulin growth factor; ITT, intention-to-treat; MAOIs, monoamine oxidase inhibitors; NE, not evaluated; NNH, number needed to harm; NSAIDs, non-steroidal anti-inflammatory drugs; RR, risk ratio; SMD, standardised mean difference; SNRI, serotonin-noradrenalin reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.

Tramadol, a weak opioid with mild serotonin-noradrenalin reuptake inhibitor (SNRI) activity was considered by two reviews. Roskell *et al*[22] identified a single study of tramadol with paracetamol. Those in the active arm were more likely to have 30% improvement in pain (RR 1.77, 95% CI 1.26 to 2.48). *Tramadol evaluation: weak for (100% agreement)*.

The literature search did not identify any reviews on corticosteroids, strong opioids, cannabinoids and antipsychotics. The committee made a 'strong against' evaluation (100% agreement) regarding the use of strong opioids and corticosteroids in patients with fibromyalgia on the basis of lack of evidence of efficacy and high risk of side effects/addiction reported in individual trials.

Evaluation of non-pharmacological therapies; complementary and alternative medicines and therapies

Acupuncture

Eight reviews included up to 16 trials and 1081 participants. One high-quality review included nine trials, with 395 patients, and demonstrated that acupuncture, added to standard therapy, resulted in a 30% (21%, 39%) improvement in pain.[70] Electric acupuncture was also associated with improvements in pain (22%; 4% to 41%) and fatigue (11%; 2% to 20%). Some adverse events were reported, but these were commonly mild and transient. There is little understanding of the active component of acupuncture, and the evidence supporting the use of real versus sham acupuncture was less consistent. *Acupuncture evaluation: weak for (93% agreement)*.

Ann Rheum Dis: first published as 10.1136/annrheumdis-2016-209724 on 4 July 2016. Downloaded from http://ard.bmj.com/ on February 3, 2023 by guest. Protected by copyright.

Table 2 Overview of results from selected systematic reviews of non-pharmacological; complementary and alternative medicine and therapy trials

Treatment (review reference)	No. of trials (no. of participants*) Review quality	Dosages; durations of treatment	Overall trial quality†	Safety and comments
Acupuncture[70]	9 (395) AMSTAR=11	Treatment sessions ranged from 3 to 13 weeks (median=4), with needle retention ranging from 20 to 30 min. Only one study provided journal references for the acupuncture point selection, and the description of the type of needle stimulation/ manipulation was clear in only three studies.	Moderate	One in six people who had acupuncture, and one in three controls, reported adverse events. Such events were minor and lasted less than one day. No serious adverse events were reported in any trials.
Biofeedback[92]	7 (321) AMSTAR=8	EMG biofeedback. Individual sessions varied between 45 and 180 min, and the number of sessions varied between 6 and 16. EEG biofeedback. 20–22 sessions of (where reported) 30 min duration.	Poor	Only two‡ trials reported adverse event data. 4% of patients in one trial receiving EMG biofeedback reported stress. And 74% of patients in another, receiving EEG biofeedback reported a variety of side effects, including: headache, fatigue and sleep problems.
Capsaicin[94]	2 (153) AMSTAR=5	Topical application of *Capsicum annuum L*. cream, either 0.025% capsaicin for 4 weeks or 0.075% for 12 weeks.	Not reported	Patients reported moderate, transient, burning or stinging.
Chiropractic[89]	3 (102) AMSTAR=4	Little detail is given for any trials, but treatment elements included massage, stretching, spinal manipulation, education and resistance training.	Low	Around 50% of patients experience mild-to-moderate transient adverse effects after spinal manipulation.§
CBT[57]	23 (2031) AMSTAR=11	Median duration of therapy=10 weeks, with a median number of 10 sessions, and median total hours=18 hours. All but two studies delivered therapy face to face. Median follow-up (where this was performed 17/23 studies)=6 months.	Low	The assessment of safety in most studies was insufficient. Two studies reported dropout due to worsening of comorbid mental disorders. However, CBT is generally considered safe.
Exercise[41]	34 (2276) AMSTAR=9	Exercise programmes lasting 2.5–24 weeks. Aerobic exercise for ≥20 min, once a day (or twice for ≥10 min), 2–3 days a week. Strength training with ≥8 repetitions per exercise, 2–3 times a week.	Moderate	Although patients may initially notice a deterioration in symptoms, exercise is generally considered safe, especially when practised under supervision.
Hydrotherapy/spa therapy[76]	10 (446) AMSTAR=9	Wide variation in precise treatment strategy between trials. Most consisted of water or mud baths at body temperature 36–37°C, or slightly above (40–45°C), with a median treatment time of 240 min (range 200–300), over several weeks.	Low	Three studies reported no side effects of treatment; one reported slight flashes in 10% of the patients. The remaining trials did not explicitly mention safety.
Hypnotherapy[91]	4 (152) AMSTAR=11	Some variation between trials ranging (where reported) from 300 to 420 min, delivered over 10–26 weeks.	Good	Adverse events were not reported in any of the trials.
Massage[63]	9 (404) AMSTAR=7	Massage therapy time lasted 25–90 min, with between 1 and 20 massage sessions in total.	Low to moderate	No adverse events were reported in any of the trials.
Meditative movement[80]	7 (362) AMSTAR=9	Wide variation in treatments between trials, and included yoga, tai chi, qigong or body awareness therapy. Median (range) duration of treatment=16 (6–24) hours, over 4–12 weeks.	Moderate	Although no serious adverse events were reported, six participants (3.1%) withdrew from the trials because of adverse events (increase of pain; muscle inflammation; chlorine hypersensitivity). The review authors concluded that the acceptance and safety of all types of meditative movement therapies were high.
Mindfulness/mind–body therapy[84]	6 (674) AMSTAR=9	Some variation between trials. Single 2–3.5 hours session per week, for 8–10 weeks. Four out of six programmes also included daily home practice (30–45 min) plus a single all-day retreat.	Low	Safety was assessed and reported in none of the trials.
Multicomponent therapy[60]	9 (1119) AMSTAR=9	Enormous variation in treatment strategies between trials. Most included different combinations of exercise (land and/or water based); education; relaxation; and/or some other specific therapeutic component (eg, Tai Chi; or massage).	Moderate	No adverse events were reported in any of the trials.
SAMe[93]	1 (44) AMSTAR=6	400 mg tablet, twice a day, for 6 weeks.	Moderate	Mild adverse effects such as stomach upset and dizziness were reported.
Other: guided imagery[91]	1 (48) AMSTAR=9	Audiotape-led, individual, guided imagery: 30 min daily for 6 weeks recommended. Median of 44 exercises (range 37–136).	Good	Adverse events were not reported.
Other: homeopathy[98]	4 (163) AMSTAR=7	Variation between trials. Two studied individualised homeopathic treatment, consisting of an initial consultation (and treatment), plus follow-up interviews every 4–8 weeks. Two studied *Arnica montana*, *Bryonia alba* or *Rhus toxicodendron* (potency 6c) daily for between 1 and 3 months.	Low to moderate	No information was provided on safety.

*Total number of persons randomised.
†According to the method of quality evaluation used in the review.
‡Elsewhere in the review, it reports that three studies reported on adverse events. However, in the table where these data are presented, it is only clear for two. However, in a third trial, there were no dropouts due to side effects.
§These data were not contained in this review. The initial recommendation for chiropractic was weak against. However, after discussion, this was downgraded to strong against due to potential safety concerns.
CBT, cognitive behavioural therapy; EMG, electromyographic; SAMe, *S*-adenosyl methionine.

Ann Rheum Dis: first published as 10.1136/annrheumdis-2016-209724 on 4 July 2016. Downloaded from http://ard.bmj.com/ on February 3, 2023 by guest. Protected by copyright.

Biofeedback

Two reviews included up to seven trials and 307 participants. Glombiewski *et al*[92] reviewed seven studies, comprising 321 participants. Treatment sessions varied from 6 to 22; with control therapy comprising sham biofeedback, attention control, medication and treatment as usual. Biofeedback was effective in reducing pain intensity (Hedges' g=0.79; 0.22 to 1.36), although all trials were poor quality. There was no evidence of effectiveness in terms of fatigue or sleep and subgroup analysis suggested that any effect was limited to electromyographic (0.86; 0.11 to 1.62) rather than electroencephalographic biofeedback (0.71; −0.37 to 1.8). *Biofeedback evaluation: weak against (100% agreement).*

Capsaicin

Two reviews included two trials and 153 participants. The most recent review, a narrative review of two trials, considered data on 153 patients.[94] Both showed some evidence of positive effect in terms of pain relief, although results were not consistent for other outcomes. Capsaicin gel is generally considered safe, although many users report a mild burning sensation when applied to the skin. However, the number of patients and trials was small and was therefore limited in the extent to which they can provide evidence for toxicity. *Capsaicin evaluation: weak against (86% agreement).*

Chiropractic

Three reviews included up to 13 trials and 102 participants. The most recent review summarised three studies.[89] One study was an open pilot study, one quasi-randomised and in the third no between-group differences were observed in terms of pain. The studies were poor quality and lacked robust interpretable data. *Chiropractic evaluation: strong against (93% agreement).*

Cognitive behavioural therapies

Five reviews included up to 30 trials and at least 2031 participants. One high-quality review included 23 trials, comprising >2000 patients, although the quality of individual trials was reported as generally poor.[58] Cognitive behavioural therapies (CBTs) were effective in reducing pain (−0.29; −0.49 to −0.17) and disability (−0.30; −0.51 to −0.08) at the end of treatment compared with a variety of controls groups, and results were sustained long term. *Behavioural therapy evaluation: weak for (100% agreement).*

Exercise

Twenty reviews included up to 34 trials and at least 2494 participants.[ii] The largest, a Cochrane review, considered 47 different exercise interventions.[41] Aerobic exercise was associated with improvements in pain (0.65; −0.09 to 1.39) and physical function (0.66; 0.41 to 0.92). Busch *et al*[42] reviewed five trials with 219 participants and concluded that resistance training resulted in a significant improvement in pain (−3.3 cm on a 10 cm scale; −6.35 to −0.26) as well as function compared with control. There is some consistency with regard to aerobic and strengthening exercises, although insufficient evidence to suggest superiority of one over the other; land and aquatic exercise appear equally effective.[56] *Exercise therapy evaluation: strong for (100% agreement).*

[ii]It is unclear from some of the reviews how many participants were included. The number of participants represents the minimum about which we can be confident.

Hydrotherapy/spa therapy

Four reviews included up to 21 trials and 1306 participants. One high-quality review included 10 trials, 446 participants and compared a median of 4-hour hydrotherapy (range 200–300 min) against various comparators.[76] There was a significant improvement in pain (−0.78; −1.42 to −0.13) at the end of therapy, maintained in the longer term (median 14 weeks), although the review authors noted that no trials conducted an ITT analysis. There was consistency with regard to the evidence for hydrotherapy and balneotherapy, although little evidence to suggest superiority of one over the other.[77] *Hydrotherapy evaluation: weak for (93% agreement).*

Hypnotherapy

One review included four trials, although the number of participants is unclear.[91] Although six trials of hypnotherapy and/or guided imagery were reviewed, only four examined hypnotherapy in isolation. Median treatment duration (where reported) was 360 min and hypnotherapy was compared with a variety of control therapies: cognitive intervention, active control (physical therapy/massage/relaxation/autogenic training) and treatment as usual. A meta-analysis is presented on all six trials, and isolated data for hypnotherapy are not presented. Two of the four hypnotherapy trials report some significant benefit in terms of pain, the other two demonstrate null, non-significant results. *Hypnotherapy evaluation: weak against (86% agreement).*

Massage

Six reviews have been reported and one meta-analysis with nine trials and 404 patients[63] with sessions lasting 25–90 min, and treatment duration ranging from 1 to 24 weeks (median 5 weeks). Comparator treatments included transcutaneous electrical nerve stimulation (TENS), standard care, guided relaxation and acupuncture. Methodological problems were noted with all of the studies, only four were at low risk of bias in terms of random allocation and only two were analysed as ITT. Overall, massage was not associated with a significant improvement in pain (0.37; −0.19 to 0.93), and of the two ITT analyses, one favoured massage and one favoured control (both significant). A subgroup analysis revealed some evidence of a positive effect with massage of ≥5 weeks duration, although this was based solely on lower-quality trials. *Massage evaluation: weak against (86% agreement).*

Meditative movement

Six reviews, including up to eight trials and 559 participants, focused on qigong, yoga, tai chi or a combination of these therapies. However, there was insufficient evidence to make individual recommendations. One review included seven trials, with 362 participants randomised to tai chi, yoga, qigong or body awareness therapy.[80] Total treatment time ranged from 12 to 24 hours and was compared with a variety of controls, including treatment as usual and active control groups (aerobics, wellness education and stretching). At the end of therapy, improvements were seen in sleep (−0.61; −0.95 to −0.27) and fatigue (−0.66; −0.99 to −0.34) some of which were maintained in the longer term. *Meditative movement evaluation: weak for (71% agreement).*

Mindfulness/mind–body therapy

Six reviews included up to 13 trials and 1209 participants. One recent review, a meta-analysis of six trials, with 674 patients[84] provided evidence that mindfulness-based stress reduction

Ann Rheum Dis: first published as 10.1136/annrheumdis-2016-209724 on 4 July 2016. Downloaded from http://ard.bmj.com/ on February 3, 2023 by guest. Protected by copyright.

resulted in improvements in pain (−0.23; −0.46 to −0.01) immediately post treatment compared with usual care and compared with active control interventions (−0.44; −0.73 to −0.16). However, these effects were not robust against bias. *Mindfulness/mind–body therapy evaluation*: *weak for (73% agreement)*.

Multicomponent therapy

Two reviews including up to 27 trials and 2407 participants examined the additional benefit of combining therapies compared with individual therapy. Häuser *et al*[60] conducted a review of management involving both educational or psychological therapies and exercise. In a meta-analysis of nine trials and 1119 patients, multicomponent therapy was effective in reducing pain (−0.37; −0.62 to −0.13), and fatigue, immediately post treatment, compared with waiting list, relaxation, treatment as usual and education. However, effects were short-lived. *Multicomponent therapy evaluation: weak for (93% agreement)*.

S-Adenosyl methionine

Two reviews each included one trial with, in combination, 74 participants. De Silva *et al*[93] reported that, after the end of treatment, significant improvements were observed in pain and fatigue compared with placebo. Sim and Adams[52] reviewed a trial comparing *S*-adenosyl methionine (SAMe) with TENS but data on the main trial comparison are omitted. Side effects are usually mild and infrequent. However, the number of patients and trials was small and therefore cannot provide a robust assessment of toxicity and safety. *SAMe evaluation: weak against (93% agreement)*.

Other complementary and alternative therapies

Three reviews of guided imagery included up to six trials and 357 participants. The highest quality, including only one trial, provided some evidence that guided imagery may be effective in reducing pain (−1.52; −2.17 to −0.87).[90] Two reviews of homeopathy included four trials and 163 participants.[97 98] Both contained a review including only four randomised trials, each of which showed some benefit of homeopathy, on some outcomes. However, none of the individual trials were without serious flaws. *Other complementary and alternative therapies (guided imagery, homeopathy): strong against (93% agreement)*.

Reviews were identified that examined electrothermal and phototherapeutic therapy;[99] phytothermotherapy;[100] music therapy, journaling/storytelling[103] and static magnet therapy,[101] although each was insufficient to allow a recommendation. Marlow *et al*[102] examined the effectiveness of transcranial magnetic and/or direct current stimulation. Eight trials included 244 participants, although not all were analysed by ITT, and appropriate group comparisons were not presented for all studies. Overall, there was little evidence to support either therapy, and several studies reported an unacceptably high rate of adverse events and/or discontinuation due to headache.

EULAR revised recommendations

In terms of overall principles, we recommend, based on unanimous expert opinion, that optimal management requires prompt diagnosis and providing the patient with information (including written material) about the condition. There should be a comprehensive assessment of pain, function and the psychosocial context. Management should take the form of a graduated approach with the aim of improving health-related quality of life. It should focus first on non-pharmacological modalities. This is based on availability, cost, safety issues and patient preference.

We have used the evaluation of individual therapies (above) to make 10 specific recommendations, all based on evidence from systematic reviews and all but one from meta-analysis. The recommendations are given in table 3, and a flow chart of how these therapies may be used in management is shown in figure 2.

We were unanimous in providing a 'strong for' recommendation for the use of exercise, particularly given its effect on pain, physical function and well-being, availability, relatively low cost and lack of safety concerns. The available evidence did not allow us to distinguish between the benefits of aerobic or strengthening. We gave 'weak for' recommendations in relation to meditative movement therapies (which improved sleep, fatigue and quality of life) or mindfulness-based stress reduction (which improved pain and quality of life); the physical therapies acupuncture or hydrotherapy for which there was evidence that they improved pain/fatigue and pain/quality of life, respectively. The effects seen in pragmatic trials of such therapies will include specific and non-specific effects, and it is not possible to disentangle these. There were some non-pharmacological therapies we did not recommend because of lack of effectiveness and/or low study quality: biofeedback, capsaicin, hypnotherapy, massage, SAMe and other complementary and alternative therapies. We provided a 'strong against' evaluation for chiropractic based on safety concerns.

In case of lack of effect of the above therapeutic approaches, we recommend individualised treatment according to patient need. Psychological therapies ('weak for') should be considered for those with mood disorder or unhelpful coping strategies: CBT was effective at producing modest, long-term reductions in pain, disability and improving mood. Pharmacological therapies (all 'weak for') should be considered for those with severe pain (duloxetine, pregabalin, tramadol) or sleep disturbance (amitriptyline, cyclobenzaprine, pregabalin). Multimodal rehabilitation ('weak for') programmes should be considered for those with severe disability—in comparison to individual therapies, those that were multimodal improved a range of short-term outcomes. We did not recommend several pharmacological therapies including NSAIDs, MAOIs and SSRIs because of lack of efficacy and specifically gave a 'strong against' evaluation to growth hormone, sodium oxybate, strong opioids and corticosteroids based on lack of efficacy and high risk of side effects.

DISCUSSION

The previous EULAR recommendations provided an important milestone in the management of fibromyalgia. There were nine recommendations, but only three were supported by strong evidence from the scientific literature; most were based on expert opinion. Since that time, there have been a considerable number of trials published addressing issues in the management of fibromyalgia. The availability of systematic reviews and meta-analysis of randomised controlled trials (RCTs) for all the most common approaches to management allowed us to concentrate on these.

Comparison with 2007 EULAR recommendations

Despite the very large increase in the amount of trial data and summarised in meta-analyses, there are no major changes to the approach of managing patients with fibromyalgia, although we provide new evidence in support for some additional non-pharmacological therapies. In addition, all the recommendations are now firmly evidence based. We now recommend that non-pharmacological therapy should be first-line therapy and then if there is a lack of effect that there should be individualised

Ann Rheum Dis: first published as 10.1136/annrheumdis-2016-209724 on 4 July 2016. Downloaded from http://ard.bmj.com/ on February 3, 2023 by guest. Protected by copyright.

Table 3 Recommendations

Recommendation	Level of evidence	Grade	Strength of recommendation	Agreement (%)*
Overarching principles				
Optimal management requires prompt diagnosis. Full understanding of fibromyalgia requires comprehensive assessment of pain, function and psychosocial context. It should be recognised as a complex and heterogeneous condition where there is abnormal pain processing and other secondary features. In general, the management of FM should take the form of a graduated approach.	IV	D		100
Management of fibromyalgia should aim at improving health-related quality of life balancing benefit and risk of treatment that often requires a multidisciplinary approach with a combination of non-pharmacological and pharmacological treatment modalities tailored according to pain intensity, function, associated features (such as depression), fatigue, sleep disturbance and patient preferences and comorbidities; by shared decision-making with the patient. Initial management should focus on non-pharmacological therapies.	IV	D		100
Specific recommendations				
Non-pharmacological management				
Aerobic and strengthening exercise	Ia	A	Strong for	100
Cognitive behavioural therapies	Ia	A	Weak for	100
Multicomponent therapies	Ia	A	Weak for	93
Defined physical therapies: acupuncture or hydrotherapy	Ia	A	Weak for	93
Meditative movement therapies (qigong, yoga, tai chi) and mindfulness-based stress reduction	Ia	A	Weak for	71–73
Pharmacological management				
Amitriptyline (at low dose)	Ia	A	Weak for	100
Duloxetine or milnacipran	Ia	A	Weak for	100
Tramadol	Ib	A	Weak for	100
Pregabalin	Ia	A	Weak for	94
Cyclobenzaprine	Ia	A	Weak for	75

*Percentage of working group scoring at least 7 on 0–10 numerical rating scale assessing agreement.

therapy according to patient need, which may include pharmacological therapy.

Comparison with other recommendation

There are three recent guidelines on the management of FM from Canada, Israel and Germany that have been compared with respect to their recommendations.[105] These guidelines and our EULAR recommendations are in agreement on the principles of approach to management, the need for tailored therapy to the individual and the first-line role of non-pharmacological therapies. There are differences between our guidelines and previous guidelines, which can partly be explained by us using more recently available evidence. There are differences in the strength of recommendations relating to pharmacological therapies: anticonvulsants and SNRIs were strongly recommended by the Canadian and Israeli guidelines while the German and these EULAR guidelines provide a weak recommendation. There are also differences in relation to individual non-pharmacological therapies across guidelines in terms of whether they were assessed. For example, meditative movement is strongly recommended by the German guidelines, but recommended only for a minority of patients in Israel, while these EULAR guidelines provide a 'weak for' recommendation.

The committee recommended that an update is conducted after 5 years in order to determine whether for those therapies with relatively little current evidence further trials have been conducted and, second, whether any new therapies have emerged for the management of fibromyalgia.

Research priorities

In the course of discussion, we identified important questions in terms of guiding management where there was either insufficient (or often no) evidence base to guide decisions, that is, 'research gaps'. We discussed their relatively priority taking into account their potential to guide management, the likelihood that such studies could be conducted and were likely to be funded. We identified five such priority questions:

- Which type of exercise is most effective: strength and/or aerobic training?
- Are combined pharmacological and non-pharmacological approaches to management more effective than single-modality management?
- Are there characteristics of patients with fibromyalgia that predict response to specific therapies?
- How should fibromyalgia be managed when it occurs as a comorbidity to inflammatory arthritis?
- What aspects of a healthcare system optimise outcome for patients (who is best for the management of FM patients)?

Some of these questions are best answered by RCTs. Given, however, the expense of such studies and that they can take almost 10 years from identifying the questions to be answered to results being obtained, alternatives including registers and observational studies should be considered. These can be complemented by qualitative studies to determine the needs of patients.

Dissemination

These recommendations will be disseminated by the international working group through national rheumatology societies. This will include scientific meetings, newsletters and continuing education programmes. We will produce a summary of the recommendations suitable for dissemination through EULAR-affiliated patient groups and through national patient societies. We will investigate assessing agreement with the recommendations in the target population.

History and physical examination
Diagnosis of fibromyalgia
if needed to exclude treatable comorbidities:
• Laboratory and / or radiological exams
• Referral to other specialists
Patient education and information sheet
if insufficient effect
Physical therapy with individualised graded physical exercise (can be combined with other recommended non-pharmacological therapies such as hydrotherapy, acupuncture)
if insufficient effect
Reassessment of patient to tailor individualised treatment
Additional individualised treatment
Pain-related depression, anxiety, catastrophizing, overly passive or active coping
Severe pain / sleep disturbance
Severe disability / sick-leave
Psychological therapies
Pharmacotherapy
Multimodal rehabilitation programs
• Mainly cognitive behavioural therapy.
• For more severe depression / anxiety consider psycho-pharmacological treatment
Severe pain
• Duloxetine
• Pregabalin
• Tramadol (or in combination with paracetamol)
Severe sleep problems
• Low dose amitriptyline
• Cyclobenzaprine or
• Pregabalin at night

Figure 2 Management recommendations as flow chart.

SUMMARY

In summary, these revised EULAR recommendations newly incorporate a decade of evidence in relation to the pharmacological and non-pharmacological management of fibromyalgia. They allow EULAR to move from recommendations that are predominantly based on expert opinion to ones that are firmly based on scientific evidence from high-quality reviews and meta-analyses. Despite this evidence, however, the size of effect for many treatments is relatively modest. We propose focusing on the research priorities we outline to address issues clarifying to whom certain interventions may best be delivered, their effect in combination, matching patients to therapies and the organisation of healthcare systems to optimise outcome.

Contributors GJM, FA, PS-P, EC and GTJ were applicants on the grant. EF and LED undertook the literature search and together with FA identified eligible reviews. EF, LED, FA and CK evaluated the quality of each of the eligible reviews. GTJ led the evaluation of non-pharmacological therapies and FA and CK led the evaluation of pharmacological therapies. GJM drafted the manuscript with input from GTJ, WH, EC, CK and EK. All authors (with the exception of FA and EF) participated in a 2-day project meeting, and all authors made important intellectual contributions to the manuscript.

Funding The project was funded by EULAR.

Competing interests CK undertook work in this project supported by a fellowship from the Swiss Society for Rheumatology. SP has received personal fees from Pierre Fabre, Pfizer, Eli Lilly and Jazz pharmaceutical (advisory boards and research activities). EC has received personal fees from Pfizer, Eli Lilly and Tonix (advisory boards and speaker fees). WH has received personal fees from MSD and Grünenthal (speaker fees), was head of the steering committee of the German guidelines on fibromyalgia and is a member of the medical board of the German Fibromyalgia Association. GJM has received personal fees from Pfizer (research activities). EK reports personal fees from Lundbeck, Orion and research funding from Eli Lilly. GMM reports personal fees from Pfizer, A Menarini, Hospiri and BMS, and has received research funding from AbbVie and Pfizer. PS-P reports personal fees from Abbott, Roche, Pfizer, UCB, MSD and has received research funding from Pfizer, UCB, Roche.

Provenance and peer review Not commissioned; externally peer reviewed.

ORIGINAL ARTICLE

The American College of Rheumatology Preliminary Diagnostic Criteria for Fibromyalgia and Measurement of Symptom Severity

FREDERICK WOLFE,[1] DANIEL J. CLAUW,[2] MARY-ANN FITZCHARLES,[3] DON L. GOLDENBERG,[4] ROBERT S. KATZ,[5] PHILIP MEASE,[6] ANTHONY S. RUSSELL,[7] I. JON RUSSELL,[8] JOHN B. WINFIELD,[9] AND MUHAMMAD B. YUNUS[10]

This criteria set has been approved by the American College of Rheumatology (ACR) Board of Directors as Provisional. This signifies that the criteria set has been quantitatively validated using patient data, but it has not undergone validation based on an external data set. All ACR-approved criteria sets are expected to undergo intermittent updates.

As disclosed in the manuscript, these criteria were developed with support from the study sponsor, Lilly Research Laboratories. The study sponsor placed no restrictions, offered no input or guidance on the conduct of the study, did not participate in the design of the study, see the results of the study, or review the manuscript or submitted abstracts prior to the submission of the paper. The recipient of the grant was Arthritis Research Center Foundation, Inc. The authors received no compensation. The ACR found the criteria to be methodologically rigorous and clinically meaningful.

ACR is an independent professional, medical and scientific society which does not guarantee, warrant or endorse any commercial product or service. The ACR received no compensation for its approval of these criteria.

Objective. **To develop simple, practical criteria for clinical diagnosis of fibromyalgia that are suitable for use in primary and specialty care and that do not require a tender point examination, and to provide a severity scale for characteristic fibromyalgia symptoms.**

Methods. **We performed a multicenter study of 829 previously diagnosed fibromyalgia patients and controls using physician physical and interview examinations, including a widespread pain index (WPI), a measure of the number of painful body regions. Random forest and recursive partitioning analyses were used to guide the development of a case definition of fibromyalgia, to develop criteria, and to construct a symptom severity (SS) scale.**

Results. **Approximately 25% of fibromyalgia patients did not satisfy the American College of Rheumatology (ACR) 1990 classification criteria at the time of the study. The most important diagnostic variables were WPI and categorical scales for cognitive symptoms, unrefreshed sleep, fatigue, and number of somatic symptoms. The categorical scales were summed to create an SS scale. We combined the SS scale and the WPI to recommend a new case definition of fibromyalgia: (WPI ≥7 AND SS ≥5) OR (WPI 3–6 AND SS ≥9).**

Conclusion. **This simple clinical case definition of fibromyalgia correctly classifies 88.1% of cases classified by the ACR classification criteria, and does not require a physical or tender point examination. The SS scale enables assessment of fibromyalgia symptom severity in persons with current or previous fibromyalgia, and in those to whom the criteria have not been applied. It will be especially useful in the longitudinal evaluation of patients with marked symptom variability.**

INTRODUCTION

The introduction of the American College of Rheumatology (ACR) fibromyalgia classification criteria 20 years ago began an era of increased recognition of the syndrome (1). The criteria required tenderness on pressure (tender points) in at least 11 of 18 specified sites and the presence of widespread pain for diagnosis. Widespread pain was defined as axial pain, left- and right-sided pain, and upper and lower segment pain.

Over time, a series of objections to the ACR classification criteria developed, some practical and some philosophi-

cal. First, it became increasingly clear that the tender point count was rarely performed in primary care where most fibromyalgia diagnoses occurred, and when performed, was performed incorrectly (2). Many physicians did not know how to examine for tender points and some simply refused to do so (3). Consequently, fibromyalgia diagnosis in practice has often been a symptom-based diagnosis.

Second, the importance of symptoms that had not been considered by the ACR Multicenter Criteria Committee became increasingly known and appreciated as key fibromyalgia features: for example, fatigue, cognitive symptoms, and the extent of somatic symptoms (4–7). In addition, a number of fibromyalgia experts believed that tender points obscured important considerations and erroneously linked the disorder to peripheral muscle abnormality (8). Finally, some physicians considered that fibromyalgia was a spectrum disorder and was not well served by dichotomous criteria (9).

There was still another important problem with fibromyalgia diagnosis. Patients who improved or whose symptoms and tender points decreased could fail to satisfy the ACR 1990 classification definition. It was not clear how to categorize or assess these patients. In addition, the ACR classification criteria set such a high bar for diagnosis that there was little variation in symptoms among fibromyalgia patients. These two considerations suggested the need for a broad-based severity scale that could differentiate among patients according to the level of fibromyalgia symptoms.

With all of these considerations in mind, we conducted a multicenter study of patients with a diagnosis of fibromyalgia and a control group of rheumatic disease patients with noninflammatory disorders to address the issues of fibromyalgia diagnosis and symptom severity. The objectives of this study were: 1) to identify non–tender point diagnostic criteria for fibromyalgia; these criteria are not meant to replace the ACR classification criteria, but to represent an alternative method of diagnosis; 2) to integrate severity scale–based symptoms in these new clinical criteria, built on the characteristic features of fibromyalgia; these criteria should be suitable for use in primary care and helpful in following patients longitudinally; and 3) to develop a fibromyalgia symptom severity (SS) scale.

To accomplish these objectives, we employed a 2-stage design. In the first stage, we collected an extensive set of patient and physician variables from 514 patients and controls, including an index of pain extent (widespread pain index [WPI]) and characteristic fibromyalgia symptoms. From the resultant data, models were developed for the surrogate classification criteria, diagnostic criteria, and a severity scale. In the second stage, 315 additional patients and controls were assessed by physicians with a reduced set of variables in a physician questionnaire format that could be reduced to a single page suitable for primary care use. The purpose of the phase 2 study was to see if a shortened, practical physician questionnaire would work as well in categorizing fibromyalgia as the longer, more detailed phase 1 assessments. Thus, we primarily report phase 1 data except for comparisons of classification rates and severity variables. Survey criteria, based on patient self-report, will be the subject of a separate report.

SUBJECTS AND METHODS

Study subjects and physicians. We recruited study physicians by selecting randomly from a list of 113 rheumatologists who were members of the ACR and who indicated an interest in participating in the study after an e-mail solicitation. We also included 5 physicians with known fibromyalgia expertise selected from the authors (FW, DJC, MAF, DLG, ASK, PM, ASR, IJR, JBW).

Participating physicians had to be certain that they would see 10 fibromyalgia patients and 10 noninflammatory controls within a 4-month period. They had to be experienced with fibromyalgia patients and the fibromyalgia tender point examination. All of the physicians completed a short instructional questionnaire on the Internet and satisfactorily completed a brief examination on study requirements and methods. We required that the physician, not an assistant, complete physician assessment forms, and that patient forms could only be completed by the patient.

We required the fibromyalgia study patients to have a previous diagnosis of fibromyalgia. They were enrolled as they appeared in the clinic for usual care (not by being recalled) and without consideration of current diagnosis, severity, or other characteristics. Fibromyalgia subjects must have been diagnosed with fibromyalgia by the same examining rheumatologist prior to the date of study assessment. Patients diagnosed with fibromyalgia could have been diagnosed on clinical grounds or by the ACR classification criteria (10). It was not a requirement of diagnosis to have satisfied the ACR classification criteria. Of the 30 physicians contributing valid patients to phase 1 of the study, 6 used only clinical diagnosis, 9 used only the ACR classification criteria diagnosis, and 15 diagnosed some

patients using clinical methods and some patients using the ACR methods. Among the expert physicians, 4 used clinical diagnosis, 4 used the ACR classification criteria diagnosis, and 2 used both methods.

Control subjects were patients with noninflammatory painful disorders such as degenerative neck and back pain syndromes or regional disorders, osteoarthritis, tendonitis, or similar disorders who had not been diagnosed previously as having fibromyalgia and who were of the same sex and were no more than 10 years younger or 10 years older than the fibromyalgia case. As with the fibromyalgia patients, the control subjects must have had a prior control diagnosis. Patients with any inflammatory rheumatic disorder (e.g., rheumatoid arthritis), active cancer, fractures, defined neuropathic causes of pain, or other nonrheumatic causes for pain were excluded from the study.

In phase 1, we enrolled 610 patients from 32 referring physicians between December 2, 2008, and April 30, 2009. We excluded 96 patients (15.7%) for one or more protocol violations. Two physicians enrolled fewer than 10 patients, 1 and 5 patients each, and their patients were excluded because of insufficient site enrollments. We also excluded subjects for invalid control diagnoses (n = 12) and for failure to match fibromyalgia patients with controls of the same sex within 10 years of age by sex (n = 96) by the time of study closure. After exclusions, there were 514 subjects (mean 17 and median 20 per center). From the group of physician participants there were 10 "experts," defined as having published on fibromyalgia in the medical literature.

Study variables: phase 1. We instructed study sites to have patients complete their forms before seeing the physician. Physicians were instructed not to look at the patient forms. Physicians' staff was asked to check each patient's form for completeness and request completion of missing items before the patient left the clinic.

Patient variables: phase 1. Patients were asked to indicate in which of 19 body areas they had pain during the last week. These areas were those previously described as part of the Regional Pain Scale (renamed here as the WPI) (11). We also analyzed the WPI as a categorical variable, with categories 0, 1, 2, and 3 for values of 0, 1–3, 4–6, and ≥7 of the WPI, respectively. The categories were determined by study analyses (see below).

Patients completed 7 categorical scales for symptoms over the past week that were scored as: 0 = no problem; 1 = slight or mild problems, generally mild or intermittent; 2 = moderate, considerable problems, often present and/or at a moderate level; and 3 = severe, pervasive, continuous, life-disturbing problems. Symptoms were assessed using the following words: pain, fatigue, trouble with sleep, trouble with anxiety or depression, problems awaking unrefreshed, and overall severity of your arthritis or fibromyalgia problem. In addition, patients completed 4 visual analog scales that were scored as 0–10. The scale questions and anchors were 1) severity of pain over the last week, with anchors from no pain to severe pain; 2) how much of a problem has fatigue or tiredness been for you over the past week?, with anchors from fatigue is no problem to fatigue is a major problem; 3) how much of a problem has sleep (i.e., resting at night) been for you in the past week?, with anchors from sleep is no problem to sleep is a major problem; and 4) how much of a problem has waking up unrefreshed been for you in the last week?, with anchors from waking up unrefreshed is no problem to waking up unrefreshed is a major problem. Patients also completed the Health Assessment Questionnaire II functional disability scale (12). Patients indicated the number of medications they used in the last month to help control pain, and reported the extent of morning stiffness.

We also asked patients to indicate which of the following symptoms they experienced in the last 3 months: blurred vision or problems focusing; dry eyes; ringing in ears; hearing difficulties; mouth sores; dry mouth; loss of or change in taste; headache; dizziness; fever; chest pain; shortness of breath; wheezing (asthma); loss of appetite; nausea; heartburn; indigestion or belching; pain or discomfort in the upper abdomen (stomach); liver problems; pain or cramps in the lower abdomen (colon); diarrhea (frequent, explosive watery bowel movements, severe); constipation; black or tarry stools (not from iron); vomiting; joint pain; joint swelling; low back pain; muscle pain; neck pain; weakness of muscles; tiredness (fatigue); depression; insomnia; nervousness (anxiety); seizures or convulsions; trouble thinking or remembering; easy bruising; hives or welts; itching; rash; loss of hair; red, white, and blue skin color changes in fingers on exposure to cold or with emotional upset; sun sensitivity (unusual skin reaction, not sunburn); yellow skin or eyes (jaundice); fluid-filled blisters; numbness/tingling/burning; swelling of the hands, legs, feet, or ankles (not due to arthritis); irritable bowel syndrome; faintness; frequent urination; painful urination; pain, fullness, or discomfort in the bladder region; sensitivity to bright lights, loud noises, or odors; fatigue severe enough to limit daily activity; tender lymph nodes; or frequent sore throats. We summed the positive replies to create a 0–56 count of somatic symptoms scale.

Physician variables: phase 1. Physicians were asked not to look at the forms completed by the patient. Physicians indicated their certainty of the prior diagnosis on a 0–10 scale (0 = very uncertain, 10 = very certain). They performed the ACR tender point count (0–18) (1) and completed the same painful body region scale as their patients did. They completed categorical scales for pain, fatigue, sleep disturbance, cognitive symptoms, waking unrefreshed, and overall (global) severity using the same categorical scoring as the patients did. Physicians also indicated if the patients had the following symptoms: muscle pain, irritable bowel syndrome, fatigue, cognitive problems, muscle weakness, headache, pain/cramps in the abdomen, paresthesias, dizziness, sleep problem, depression, constipation, diarrhea, interstitial cystitis, anxiety, and muscle tenderness.

We then provided the physicians a list of symptoms for reference purposes and asked them to categorize the patients as having few or no somatic symptoms, a moderate number of symptoms, or a great deal of symptoms. The reference list consisted of: muscle pain, irritable bowel

syndrome, fatigue/tiredness, thinking or remembering problem, muscle weakness, headache, pain/cramps in the abdomen, numbness/tingling, dizziness, insomnia, depression, constipation, pain in the upper abdomen, nausea, nervousness, chest pain, blurred vision, fever, diarrhea, dry mouth, itching, wheezing, Raynaud's phenomenon, hives/welts, ringing in ears, vomiting, heartburn, oral ulcers, loss of/change in taste, seizures, dry eyes, shortness of breath, loss of appetite, rash, sun sensitivity, hearing difficulties, easy bruising, hair loss, frequent urination, painful urination, and bladder spasms.

Based on the study results described below, we created an SS scale by summing the 0–3 scores of somatic symptoms, waking unrefreshed, cognition, and fatigue into a 0–12 scale.

Phase 2 study and variables. The methods and rules for physician and patient recruitment were the same for the second phase, except that the authors with known fibromyalgia expertise were not recruited. In addition, patients did not complete questionnaires. At the time of study closure, 315 valid patients had been enrolled. The phase 2 form was simplified and completed only by the physician. It contained the following items: a categorical WPI and a question about widespread pain. Physicians were provided with a list of the widespread pain regions (scored as 0–3, 4–6, 7–10, or ≥11), but could not score the individual regions. Physicians performed and recorded a tender point examination; indicated the presence or absence of muscle pain, muscle tenderness, and irritable bowel syndrome; and provided a rating of the extent of somatic symptoms (few or no symptoms, a moderate number of symptoms, or a great deal of symptoms). For reference, a list of 41 symptoms was supplied on the questionnaire. Finally, we included categorical scales for sleep disturbance, unrefreshed sleep, cognitive problems, and fatigue, with scoring as described above.

Statistical methods. On completion, study forms were faxed to the National Data Bank for Rheumatic Diseases, Wichita, Kansa, for processing. They were reviewed for missing data, and if such data were found, the examining physician was contacted immediately for corrections, if possible. Missing patient data and physician data that were not correctable within one week were left as missing. Missing data were rare: in phase 1, 81.7% of patients had no missing data, 12.8% had 1 missing data point, and 1.6% had 3–8 missing data points.

In phase 1 analyses, we considered 3 groups of classifier variables: a short set of variables, an intermediate set, and a complete set. The short set included the WPI and categorical scales for pain, fatigue, sleep disturbance, mood, cognitive problems, somatic symptoms, and unrefreshed sleep. The intermediate set included all of the variables in the short set plus all of the individual somatic symptoms. The complete set included all of the study variables. We anticipated that, because of the need for simplicity, the criteria and severity scales would probably come from the short set. We analyzed the intermediate set under the consideration that the individual symptoms might also be important. The complete set allowed us to compare the 3 sets as to their classifying value and to understand what might be lost in shortening the set of variables.

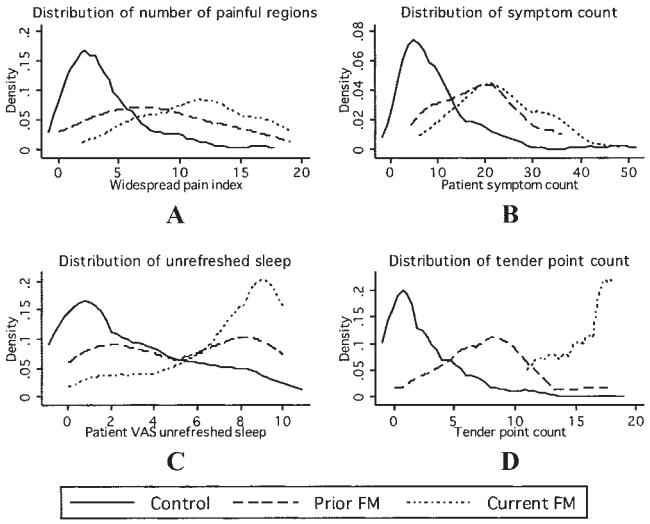

Figure 1. Distribution of key fibromyalgia (FM) variables in controls and patients with current or prior FM (phase 1). VAS = visual analog scale.

Comparisons between groups used *t*-tests, regression analyses with dummy variables, and chi-square tests, as indicated. Spearman's coefficients were used for correlation analyses. Data were analyzed using Stata, version 10.1 (StataCorp), and the R statistical package, version 2.81. Random forest analysis was used to determine variable importance and "out-of-bag" error rates (10,11) using the R statistical package. The out-of-bag error rate is a robust measure of misclassification error. Variable importance is described by the mean decrease in accuracy criterion or the Gini Index, and it represents a ranking of variables in terms of their importance as predictors. The mean decrease in accuracy is thought to be a better measure: ". . . the Gini Index reflects the overall goodness of fit, while the predictive accuracy depends on how well the model actually predicts. The two are related, but they measure different things. Breiman argues that the decrease in predictive accuracy is the more direct, stable and meaningful indicator of variable importance (personal communication)" (13). Classification tree analysis used the rpart recursive partitioning R analysis programs to determine preliminary cut points for criteria variables (14). Figure 1 describes the distribution of study variables using a probability density function. The reader can think of the probability density function as a "smoothed-out" version of a histogram.

Conflict of interest and ethics. Examining physicians were each compensated $2,000 for their work in interviewing, examining, and completing study forms for 10 patients and 10 controls. The study authors received no compensation. The study was approved by the Via Christi Institutional Review Board.

RESULTS

Demographics. Physicians enrolled 258 valid patients in phase 1 whose clinical diagnosis was fibromyalgia and

* Values are the mean ± SD unless otherwise indicated. ACR = American College of Rheumatology; HAQ-II = Health Assessment Questionnaire II; VAS = visual analog scale.
† Sum of physician somatic symptoms, physician waking unrefreshed, physician cognition, and physician fatigue.

256 who were control subjects. Fibromyalgia subjects were slightly older than controls (mean ± SD age 54.6 ± 12.9 versus 52.3 ± 12.2 years; $P = 0.035$), but did not differ by the percentage of males (8.2% versus 9.0%; $P = 0.732$), percentage of non-Hispanic whites (86.8% versus 85.9%; $P = 0.770$), or education level (mean ± SD 14.2 ± 2.1 versus 14.3 ± 2.2 years; $P = 0.517$).

Diagnosis and diagnostic methods. ACR classification criteria were used in 63.6% of fibromyalgia diagnoses and clinical diagnosis was used in 36.4% of fibromyalgia diagnoses. At the time of the study examination, 74.5% of patients who had been previously diagnosed with fibromyalgia satisfied the ACR classification criteria and 2.0% of controls satisfied the ACR classification criteria. Based on these data, we categorized patients into 3 groups based on prior diagnosis and ACR classification criteria status: 196 patients (38.1%) with current fibromyalgia (ACR classification criteria positive, physician fibromyalgia diagnosis positive), 67 patients (13.0%) with prior fibromyalgia (ACR classification criteria negative, physician fibromyalgia diagnosis positive), and 251 patients (48.1%) who were neither current nor prior fibromyalgia patients (control subjects) (Table 1). Using a 0–10 physician certainty of prior diagnosis scale, the mean certainties were: fibromyalgia 9.4, prior fibromyalgia 8.7, and control diagnosis 9.1. Patients previously diagnosed by clinical criteria were more likely to be classified as prior fibromyalgia (38.3%) compared with patients previously diagnosed by the ACR classification criteria (18.9%; $P < 0.001$). The proportion of patients who were controls or had prior or current fibromyalgia did not differ between the group of 10 expert physicians and the 20 clinical rheumatologists ($P = 0.640$).

Characteristics of patients by fibromyalgia status. There was a clear difference in clinical findings and symptom severity among the groups, the current fibromyalgia patients having the greatest symptom severity with prior fibromyalgia generally occupying the severity scale midpoint between current fibromyalgia and controls (Table 1). However, for the count of patient-endorsed somatic symptoms, the physician somatic symptom scale, and the SS scale, prior fibromyalgia patients had scores that were somewhat closer to current fibromyalgia patients than to control subjects. Figure 1 shows differences between groups for key variables. The tender point count (Figure 1D) demonstrates the clearest distinction between groups, followed by unrefreshed sleep (Figure 1C). Prior and current fibromyalgia patients had similar distributions of somatic symptom counts (Figure 1B), while prior fibromyalgia had the WPI shifted somewhat to the left (Figure 1A). Taken as a whole, these data show that approximately 25% of patients considered to have fibromyalgia by their physicians do not satisfy ACR classification criteria for fibromyalgia, and that they appear to have an intermediate severity position between fibromyalgia patients and control subjects, except for somatic symptoms.

Misclassification rates and fibromyalgia classifiers. To determine variables that best identify fibromyalgia and to examine the predictive power of study variables without the use of tender points, we divided the subjects into ACR

Table 2. Random forest out-of-bag misclassification rates for physician and patient variable groups in the diagnosis of ACR 1990 classification criteria–positive fibromyalgia (phase 1)*

Variable group	Error rate (continuous WPI)	Error rate (categorical WPI)	Error rate (no WPI, no muscle variables)	Error rate (no WPI, no muscle tenderness)	Error rate (no WPI)
Physician evaluator, %					
Complete	6.2	6.4	NA	NA	NA
Intermediate	6.4	7.3	16.1	14.0	10.3
Short	8.9	10.3	18.4	NA	NA
Patient evaluator, %					
Complete	12.7	NA			
Intermediate	14.1	NA			
Short	13.9	NA			

* Prior fibromyalgia cases are excluded from the analysis. ACR = American College of Rheumatology; WPI = widespread pain index; complete group = all study variables; NA = not applicable; intermediate group = short group variables plus all individual somatic symptoms; short group = WPI and categorical scales for pain, fatigue, sleep disturbance, mood, cognitive problems, somatic symptoms, and unrefreshed sleep.

classification criteria–positive (all patients satisfying the ACR classification criteria) and ACR classification criteria–negative cases (all controls satisfying the ACR criteria), after excluding patients who physicians designated as having fibromyalgia but who did not satisfy the ACR classification criteria. We then used random forest analyses to rank physician predictors of fibromyalgia by their importance and to obtain misclassification rates. We examined the WPI as a continuous variable (0–19) and also after splitting it into categories at 0, 1–3, 4–6, and ≥7. In these analyses, we examined the complete set of variables, an intermediate set, and a short set (Table 2).

Depending on the number of variables in the model (variable group) and whether the WPI was used as a continuous or a categorical variable, physician study variables misclassified fibromyalgia cases and controls at rates of 6.2–10.3% (Table 2). Figure 2A shows that the WPI and muscle tenderness were the most important variables in the classification of cases and noncases. These data provide an estimate of the lowest misclassification rates of surrogate criteria obtainable under optimum data mining conditions.

We next performed analyses to determine misclassification rates when muscle variables (muscle pain, muscle tenderness) and the WPI were removed from the models. Removing all of the muscle variables and the WPI resulted in a misclassification rate of 16.1% (Table 2). Using the same intermediate model but keeping muscle pain reduced the error rate to 14.0%, whereas removing the WPI but leaving all muscle pain and muscle tenderness variables resulted in a misclassification rate of 10.3%. Using the short variable list (that never contains muscle pain or muscle weakness), the misclassification rate was 18.4%. These data show that misclassification rates obtainable under optimum data mining conditions that do not contain ACR classification criteria–related variables are between 16.1% and 18.4% (14.0% if muscle pain is allowed).

Based on the information in Table 2, we selected the variables contained in the intermediate WPI categorical model (7.3% error rate) for further study because that model represented the best practical model that contained the WPI and muscle data (Table 2) and had the lowest misclassification rate. Random forest analysis provides information on variable importance and misclassification rates, but does not provide information about the optimum cut points for study variables. We then applied recursive partitioning to the data and determined that values of the WPI ≥7 best identified fibromyalgia cases and values ≤6 best identified control cases according to their ACR classification criteria status.

In addition, in the comparison of ACR classification criteria–positive versus ACR classification criteria–negative cases (excluding prior fibromyalgia), the correct classification rates for phase 1 ran between 89.0% and 92.6%, with higher rates being obtained in phase 2 analyses. When all of the patients were considered, WPI ≥7 performed about as well (83.6%) as physician diagnosis (84.1%) in the classification of fibromyalgia in phase 1, again with improvement in the phase 2 data. There was some gain obtained by including information about muscle pain or muscle tenderness. Overall, these data show that patients who satisfy the ACR classification criteria can be identified with an acceptable rate of error by the use of the WPI alone, and with very slightly better results if muscle tenderness or muscle pain is assessed.

The SS scale and fibromyalgia diagnostic criteria. To build and identify an alternative definition of fibromyalgia and to create an SS scale, we turned back to the intermediate categorical model that excluded the WPI and muscle variables (Table 2 and Figure 2B). From Figure 2B, we identified 6 categorical rating scale variables that had high importance levels (somatic symptoms, waking unrefreshed, cognition, fatigue, sleep problems, and mood). As shown in Table 3, these variables are strongly correlated with the tender point count and the WPI. For comparison, pain intensity, with correlation coefficients of 0.346 and 0.437, respectively, was less strongly correlated. We created an SS scale by summing the 0–3 scores of somatic symptoms, waking unrefreshed, cognition, and fatigue, into a 0–12 scale.

When applied to study patients, using the ACR classifi-

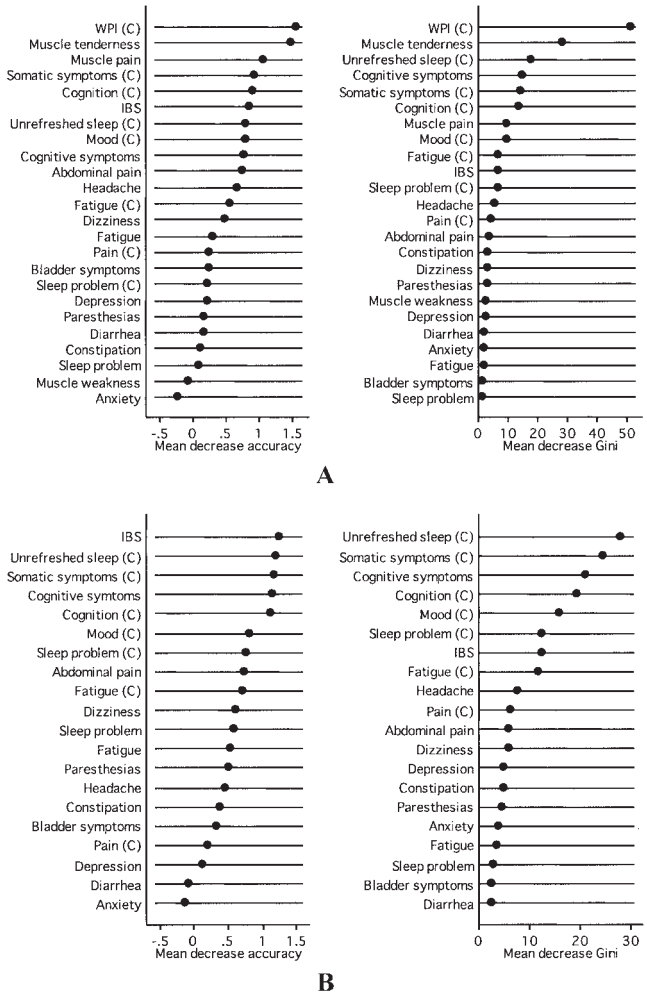

Figure 2. **A**, Variable importance (physician variables) in distinguishing fibromyalgia from controls in intermediate detail physician evaluation by random forest analysis in phase 1, including the widespread pain index (WPI) and muscle symptoms. **B**, Variable importance (physician variables) in distinguishing fibromyalgia from controls in intermediate detail physician evaluation in phase 1 by random forest analysis, excluding the Regional Pain Scale (WPI) and muscle symptoms. Other variables are present/absent conditions. Variable importance is described by the mean decrease in accuracy criterion or the Gini Index, and it represents a ranking of variables in terms of their importance as predictors. The Gini Index reflects the overall goodness of fit, while the predictive accuracy depends on how well the model actually predicts. The two are related, but they measure different things (13). The mean decrease in accuracy is thought to be a better measure. C = categorical scale; IBS = irritable bowel syndrome.

cation criteria definition of fibromyalgia, the mean ± SD SS scale score for fibromyalgia was 8.0 ± 2.6, for prior fibromyalgia was 6.0 ± 2.6, and for controls was 3.3 ± 2.2 (Table 1). The SS scale was strongly correlated with the WPI (0.733) and the tender point count (0.680), and was the strongest correlate of WPI after the tender point count, which was correlated with the WPI at 0.773 (Table 3). As shown in Figure 3, the SS scale appropriately follows the definitions of ACR classification criteria–positive fibromyalgia, prior fibromyalgia, and non-fibromyalgia, suggesting that it can categorize fibromyalgia symptom severity.

Table 3. Spearman's correlation coefficients for all study subjects (phase 1)

Variable	Tender point count	Widespread pain index
Tender point count	1.000	0.773
Widespread pain index	0.773	1.000
Symptom severity scale	0.680	0.733
Symptom severity scale*	0.672	0.713
Somatic symptoms†	0.631	0.683
Waking unrefreshed†	0.622	0.656
Cognition†	0.575	0.592
Fatigue†	0.548	0.604
Sleep problems	0.524	0.546
Mood	0.504	0.534
Pain	0.346	0.437

* Five-component symptom severity scale (includes mood).
† Component of 4-component symptom severity scale.

Fibromyalgia case definition: diagnostic criteria. We used the SS scale and the WPI to recommend a new case definition of fibromyalgia: (WPI ≥7 AND SS ≥5) OR (WPI 3–6 AND SS ≥9) (Table 4). This definition recognizes that fibromyalgia is more than just a high WPI scale by requiring an SS scale score ≥5, and recognizes that a high level (SS ≥9) of symptoms should be sufficient for diagnosis, provided that there is sufficient body pain. Using this definition, 9.1% of controls would be diagnosed as having fibromyalgia, 53.1% of prior fibromyalgia patients would be diagnosed as having fibromyalgia, and 14.1% of ACR classification criteria–positive cases would not be diagnosed as having fibromyalgia. Overall, the fibromyalgia rate among all of the study subjects would increase from 38.1% to 45.5% using the recommended definition. As shown in Table 5, using the ACR classification criteria as the gold standard, the diagnostic criteria diagnose 82.6% of cases correctly compared with the clinician's correct diagnosis rate of 84.1%.

We also used the SS scale to aid in the diagnosis of

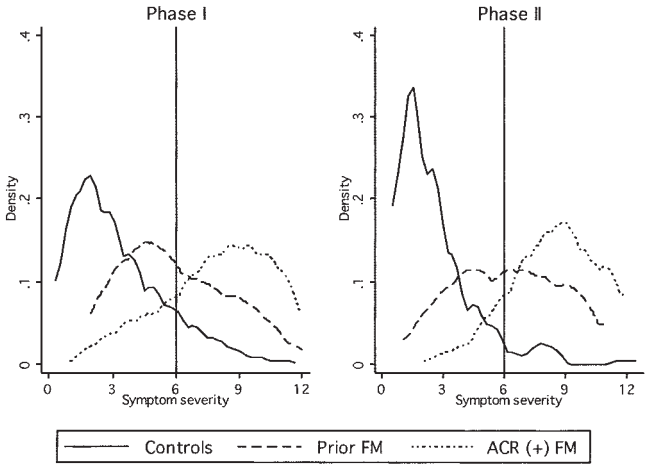

Figure 3. Distribution of severity scores using the American College of Rheumatology (ACR) 1990 classification criteria definition of fibromyalgia (FM) by category of FM diagnosis in phases 1 and 2. A symptom severity scale score >6 identifies patients satisfying the new diagnostic criteria in 92.3% of cases.

Table 4. Fibromyalgia diagnostic criteria

Criteria

A patient satisfies diagnostic criteria for fibromyalgia if the following 3 conditions are met:

1) Widespread pain index (WPI) ≥7 and symptom severity (SS) scale score ≥5 or WPI 3–6 and SS scale score ≥9.
2) Symptoms have been present at a similar level for at least 3 months.
3) The patient does not have a disorder that would otherwise explain the pain.

Ascertainment

1) WPI: note the number areas in which the patient has had pain over the last week. In how many areas has the patient had pain? Score will be between 0 and 19.

Shoulder girdle, left	Hip (buttock, trochanter), left	Jaw, left	Upper back
Shoulder girdle, right	Hip (buttock, trochanter), right	Jaw, right	Lower back
Upper arm, left	Upper leg, left	Chest	Neck
Upper arm, right	Upper leg, right	Abdomen	
Lower arm, left	Lower leg, left		
Lower arm, right	Lower leg, right		

2) SS scale score:

Fatigue
Waking unrefreshed
Cognitive symptoms

For the each of the 3 symptoms above, indicate the level of severity over the past week using the following scale:

0 = no problem
1 = slight or mild problems, generally mild or intermittent
2 = moderate, considerable problems, often present and/or at a moderate level
3 = severe: pervasive, continuous, life-disturbing problems

Considering somatic symptoms in general, indicate whether the patient has:*

0 = no symptoms
1 = few symptoms
2 = a moderate number of symptoms
3 = a great deal of symptoms

The SS scale score is the sum of the severity of the 3 symptoms (fatigue, waking unrefreshed, cognitive symptoms) plus the extent (severity) of somatic symptoms in general. The final score is between 0 and 12.

* Somatic symptoms that might be considered: muscle pain, irritable bowel syndrome, fatigue/tiredness, thinking or remembering problem, muscle weakness, headache, pain/cramps in the abdomen, numbness/tingling, dizziness, insomnia, depression, constipation, pain in the upper abdomen, nausea, nervousness, chest pain, blurred vision, fever, diarrhea, dry mouth, itching, wheezing, Raynaud's phenomenon, hives/welts, ringing in ears, vomiting, heartburn, oral ulcers, loss of/change in taste, seizures, dry eyes, shortness of breath, loss of appetite, rash, sun sensitivity, hearing difficulties, easy bruising, hair loss, frequent urination, painful urination, and bladder spasms.

clinical fibromyalgia, because Figure 3 suggests that severity scale criteria might be applicable. A severity score ≥7 correctly classifies 92.3% of cases identified by the new diagnostic criteria definition: (WPI ≥7 AND SS ≥5) OR (WPI 3–6 AND SS ≥9). When applied to the ACR classification criteria, correct classification falls to 79.2%. This

Table 5. Percentage of patients correctly classified according to ACR 1990 classification criteria status and diagnostic criteria*

Comparison	Phase 1		Phase 2	
	Prior FM excluded	All patients	Prior FM excluded	All patients
ACR classification criteria positive, FM patients		74.0		75.6
Classifying patients according to ACR 1990 classification criteria status				
ACR 1990 criteria vs. physician diagnosis		84.1		
ACR 1990 criteria vs. WPI ≥7	89.0	83.6	92.3	87.9
ACR 1990 criteria vs. WPI ≥7 plus muscle pain	89.9	84.6	95.2	90.5
ACR 1990 criteria vs. WPI ≥7 plus muscle tenderness	92.6	87.4	95.2	90.5
FM diagnostic criteria				
ACR 1990 classification criteria vs. diagnostic criteria ((WPI ≥7 AND SS ≥5) OR SS ≥9)	88.1	82.6	95.2	90.8
ACR 1990 classification criteria vs. categorical SS scale (SS ≥7)	84.3	79.2	88.8	84.5
Diagnostic criteria ((WPI ≥7 AND SS ≥5) OR SS ≥9) vs. categorical SS scale (SS ≥7)		92.3		89.2

* ACR = American College of Rheumatology; FM = fibromyalgia; WPI = widespread pain index; SS = symptom severity.

falloff is to be expected, as the definition of fibromyalgia is shifted in the new criteria definition. Using the newly proposed categorical definition for fibromyalgia, the mean ± SD SS scale score for fibromyalgia was 8.5 ± 2.0, and for non-fibromyalgia was 2.9 ± 1.6. Using the SS scale score cutoff of ≥7, the mean ± SD respective scores were 8.6 ± 1.8 and 2.8 ± 1.4.

Phase 2 validation. The ACR classification criteria were used in 74.6% of fibromyalgia diagnoses. Among patients diagnosed as having fibromyalgia, 76.0% met ACR classification criteria compared with 74.5% in the first phase of the study. We categorized the 315 patients into 3 groups based on prior diagnosis and current ACR classification criteria status: 42.2% with current fibromyalgia, 13.3% with prior fibromyalgia, and 44.4% who were neither current nor prior fibromyalgia patients. The validation sample was slightly different in the 2 phases (Figure 3), and criteria to identify ACR classification criteria cases worked slightly better in phase 2.

DISCUSSION

We are aware of the inherent problems in the diagnosis of somatic syndromes that lack objective physical or laboratory features or well-characterized pathologic findings. The utility of such diagnostic criteria is very dependent on the clinical setting. The initial ACR fibromyalgia classification criteria stipulated that chronic widespread pain was present for 3 months and it was understood that no other disease was thought by the examiner to be accounting for the chronic widespread pain. These ACR classification criteria performed well in specialty clinics and were very useful in providing some patient homogeneity for clinical trials. However, they have not been widely embraced in primary care.

The diagnostic criteria suggested here (Table 4) are not meant to replace the ACR classification criteria. Instead, they were designed to address certain realities. First, the clinical diagnosis in primary care does not ordinarily involve a tender point count or an adequately executed tender count when performed. Second, the case definition of fibromyalgia has changed somewhat with increasing recognition of the importance of cognitive problems and somatic symptoms, factors that were not even considered in the 1990 ACR classification criteria.

In developing new diagnostic criteria, we identified 2 variables that best defined fibromyalgia and its symptom spectrum: the WPI and the composite SS scale. The WPI, which strongly correlated with the tender point count and the SS scale, best identified patients diagnosed with the ACR classification criteria. We also selected the SS scale, a composite variable composed of physician-rated cognitive problems, unrefreshed sleep, fatigue, and somatic symptom count to measure fibromyalgia symptom severity. We used the WPI and the SS scale together to define fibromyalgia diagnostic criteria: (WPI ≥7 AND SS ≥5) OR (WPI 3–6 AND SS ≥9). We also used the SS scale alone to provide a measure of fibromyalgia symptom severity. In many respects, these criteria are similar in concept to those proposed by Yunus et al in 1981 (15). These authors allowed fewer tender points in the presence of many symptoms, and they stressed the importance of symptoms.

One of the important findings of the current study was that approximately 25% of diagnosed fibromyalgia patients in both phases of the study did not satisfy the ACR classification criteria, although they were considered to have fibromyalgia by their physicians. Neither the ACR classification criteria nor the diagnostic criteria suggested here provide a solution for this classification dilemma. It arises because fibromyalgia diagnosis is based on severity assessments. The loss of a tender point or a painful region for any reason, including improvement, can result in failing to meet classification or diagnostic criteria. Practically, the conundrum involves patients who have fibromyalgia but who do not meet criteria versus patients who do not have fibromyalgia because they do not meet criteria. In this respect, fibromyalgia differs from rheumatoid arthritis or systemic lupus erythematosus, illnesses that do not involve diagnosis based on symptom severity, where patients continue to have their condition even though they may subsequently not meet diagnostic criteria.

We suggest the use of the SS scale to quantify fibromyalgia symptom severity as a workable solution to this problem. As shown in Figure 3, the distribution of SS scale scores defines the 3 diagnostic categories and provides measurement of fibromyalgia symptom severity to patients who do and do not currently satisfy ACR fibromyalgia criteria. Practically, patients who have satisfied the ACR classification or diagnostic criteria at one time can be followed with the symptom scale, thereby linking current status to previous diagnosis.

In creating the SS scale we chose not to use the mood variable, although it had importance in Figures 2A and B. We chose not to include mood because we judged mood difficult to assess and because it might be a resultant feature rather than a primary feature of the illness. Although we omitted mood, it was correlated with the SS scale at 0.725 and with the components of the SS scale as follows: cognition 0.625, somatic symptoms 0.621, waking unrefreshed 0.619, and fatigue 0.612. In addition, as shown in Table 3, a 5-component SS scale that included mood did not perform as well as a 4-component scale. Unrefreshed sleep was a better measure than sleep disturbance and we recommend its use in the SS scale. However, in sensitivity analyses, it provided marginally better differentiating power; we suggest that either scale can be used, although unrefreshed sleep is better. Of the binary variables, irritable bowel syndrome, abdominal pain, and headache had variable importance. However, they added no power to correct classification and we did not include them in the diagnostic criteria.

In addition, in developing criteria for clinical diagnosis we were cognizant of the need to make the diagnostic criteria simple enough and easy enough so that they would actually be used in clinical practice. To that end, we used simple categorical scales for the symptom scale and compressed the WPI to a similar categorical scale. None of this guarantees that the scales will be used appropriately, but it is easy enough to use them appropriately, and the knowl-

edge that these are key factors will increase recognition of such important symptoms.

In designing this study, we were concerned that a simple questionnaire would lose too much information. Therefore, we used a complex series of questions and evaluation in phase 1. Based on the results in Table 2, which showed little gain from the complete data sets, we collapsed the questionnaire to categorical scales and changed the format to a form that could be used in the clinic. Results from phase 2 in Table 5 suggest that the criteria would work satisfactorily in the final format, which is included in Table 4.

Readers might wonder: why is it so difficult to make new fibromyalgia criteria? The central problem in fibromyalgia criteria is the absence of a gold standard or case definition. The ACR classification criteria, rightly criticized for circularity (16), created a de facto case definition by imposing the 11 tender point rules on top of a crude definition of widespread pain (17). Subsequent studies as well as the data of this study showed the importance of (improved) quantitative measures of body pain (18–22), and of the key variables that comprise the SS scale in characterizing fibromyalgia. The shift in the conceptualization of fibromyalgia that occurred in the clinic and in research studies, however, provided no clear case definition. In the current study, we derived an empirical case definition from the variable importance analyses. The diagnostic criteria and SS scale we have proposed shift the fibromyalgia definition somewhat toward important symptoms: first, the criteria can be satisfied by a high level of symptoms if the WPI score is not high enough; second, fibromyalgia symptoms are accorded appropriate importance by the provision of the SS scale.

The suggested diagnostic criteria create a small discordance between the older ACR classification criteria case definition and the current definition that we have proposed. However, it is clear that the ACR classification criteria are unable to provide a useful classification for the 25% of fibromyalgia cases we identified as prior fibromyalgia, something that can be somewhat ameliorated through the use of the SS scale. In addition, it should be remembered that physician diagnosis only correctly classified 84.1% of cases, while the proposed diagnostic criteria, even with shift of definition, identified 82.6% of patients correctly (Table 5).

We envision the use of the diagnostic criteria in the following ways: following a diagnosis of fibromyalgia by ACR classification or diagnostic criteria, the results of the SS scale can document baseline symptom severity. Should the patient subsequently not satisfy ACR classification or diagnostic criteria, the SS scale can be used to measure current symptom severity status and change in status without the contradiction of having a diagnosis of fibromyalgia but not satisfying fibromyalgia criteria at the same time. Of course, the SS scale can also be used at any time regardless of diagnostic status. The SS scale alone provides some diagnostic information, but does not include the WPI. It provides information as to symptom severity and it allows fibromyalgia to be seen as part of a continuum, as some have suggested. The criteria and severity scale also provide room for those who are uncomfortable with the fibromyalgia concept, as they can simply report the WPI and the SS scale.

Physicians who are used to the ACR classification criteria may be uncomfortable with the absence of a physical examination criterion in the new diagnostic criteria. However, 98.7% of the patients in the study satisfying the diagnostic criteria had a least 1 tender point and 96.3% had 3 or more tender points. Even though the new criteria do not include a physical examination criterion, all of the patients being diagnosed should have a physical examination, which may include examination of tender point sites. We would like to point out that implicit in the 1990 ACR classification criteria was the requirement that clinical examination and clinical judgment had excluded other causes of chronic widespread pain, and such an exclusion is also implicit in the proposed diagnostic criteria. It is important for physicians to perform an appropriate clinical assessment to exclude other diagnoses, and/or to identify potential coexisting rheumatic diseases that may require treatment themselves.

Although not a study requirement for enrollment, all of the patients with fibromyalgia diagnosed by physicians had symptoms for at least 3 months. However, the timeframe for the physician assessment of WPI and the SS scale was 1 week. We used this timeframe to more accurately determine the level of symptoms. The new diagnostic criteria require that patients diagnosed as having fibromyalgia will have had a similar level of symptoms for at least 3 months, in agreement with the ACR classification criteria.

Although we collected data directly from patients as well as data from physicians, patient data did not work as well in correct classification as physician data (Table 2). The best misclassification rate obtainable with patient data was 12.7% compared with 6.2% with physician data. This difference is related to the fact that it is the physician and not the patient who makes the diagnosis.

This study has a number of limitations. Although our goal was to develop simple, practical criteria for clinical diagnosis of fibromyalgia that are suitable for use in primary and specialty care, we did not study the performance of these criteria in primary care. We recommend that a followup study in the primary care setting be accomplished. We also did not test the criteria among those with other rheumatic conditions, and we recommend that this be done in the future, too. The patient population should include those with relevant differential diagnoses (i.e., other rheumatic conditions) to determine the rate of misclassification that may occur. If, as we expect, the diagnostic criteria perform well, it seems possible that the ACR classification criteria might be withdrawn.

In summary, we have developed a case definition and diagnostic criteria for fibromyalgia: (WPI $\geq$7 AND SS $\geq$5) OR (WPI 3–6 AND SS $\geq$9). This simple clinical case definition of fibromyalgia correctly classifies 88.1% of cases classified by the ACR classification criteria, and does not require a physical or tender point examination. The SS scale enables assessment of fibromyalgia symptom severity in persons with current or previous fibromyalgia, and in those to whom the criteria have not been applied. It will be especially useful in the longitudinal evaluation of patients with marked symptom variability.

ACKNOWLEDGMENTS

The authors thank Kimberly Harp of the National Data Bank for Rheumatic Diseases for her superb work with study physicians and their questionnaire submissions that insured study quality. Management of foot health in people with inflammatory arthritis: British Society for Rheumatology guideline scope

The guideline will be developed using the methods and processes outlined in Creating Clinical Guidelines: Our Protocol [1]. This development process to produce guidance, advice and recommendations for practice has National Institute for Health and Care Excellence (NICE) accreditation.

1 Why the guideline is needed

Foot problems are highly prevalent in adults, children and young people with inflammatory arthritis (IA), but their burden is often underestimated by health professionals. People with IA are often frustrated that concerns relating to their feet are ignored [2–4]. There are existing guidelines for foot health that may be applicable to IA. A regional podiatry group has developed management guidelines to support non-specialist podiatrists in the management of people with RA and related foot problems [5]. However, these guidelines are now nine years old and, while they are practitioner-facing, they relate only to RA instead of the wider spectrum of IA, do not include children and young people, and are not sensitive to the foot health needs of people from different cultural and religious backgrounds (e.g. footwear and orthotic device appearance and preferences for different materials). There are also standards embedded in the NICE guideline for RA highlighting the need to treat foot pathology [6]. These standards have an underpinning philosophy that encourages empowered self-care, patient involvement in service design, tailoring of services to patients' needs, promotion of informed choice, and

NICE accredited
www.nice.org.uk/accreditation

NICE has accredited the process used by BSR to create its clinical guidelines. The term began on 27 February 2012 and the current renewed accreditation is valid until 28 January 2023. More information on accreditation can be viewed at www.nice.org.uk/accreditation.

timely and appropriate access to services where needed. However, they do not make recommendations about specific aspects of clinical management, such as particular foot problems and different rheumatic diseases. Furthermore, there is limited guidance as to when foot health experts should be consulted and there are no recommendations on which assessments or interventions should be performed. Finally, the Arthritis and Musculoskeletal Alliance (ARMA) have previously produced generic patient-facing Standards of Care for people with musculoskeletal foot health problems [7] and children and young people with JIA [8]. These outlined what patients should expect from services at that time, and the latter recognize the need for specialist podiatry reviews for people with JIA. Despite this, neither provide clinicians with guidance for treatment and both standards are now over a decade old. A survey of non-specialist podiatrists in the UK found that over 95% were unaware of existing guidelines [9]. There is a clear need for a national evidence-based clinical guideline for foot health that is aimed at clinicians and focused on IA more widely.

This new BSR guideline will address the assessment and management of foot health in adults, children and young people with IA and will focus specifically on the healthcare setting in the UK. Clear, culturally sensitive guidance regarding evidence-based strategies for the management of foot problems in people with IA will help all clinicians to provide high-quality care for their patients, service providers, and commissioners, to ensure that adequately resourced foot health services are available to meet the needs of patients. The guideline will provide advice to enable a range of clinicians to provide first-line therapy for foot conditions where access to podiatry is limited, and advise when specialist opinions should be sought.

Key facts and figures

IA is an umbrella term encompassing a range of chronic, autoimmune conditions characterised by joint inflammation. These include RA, JIA and spondyloarthropathy (SpA) – which encompasses PsA, AS, reactive arthritis, enteropathic arthritis and undifferentiated SpA.

Despite the introduction of aggressive pharmacological therapies, foot problems frequently occur in IA. Around 90% of people with RA experience foot problems during the course of the disease, including rearfoot and forefoot deformity, tibialis posterior dysfunction, peripheral arthritis, and subluxation and dislocation of the MTP joints, leading to pain and reduced walking ability [10]. The foot is also particularly susceptible to damage in JIA. Foot-related impairment and disability has been shown to persist in over 90% of children and young people with the condition, despite intensive pharmacological therapy [11], and foot problems are also common in adults with JIA. In SpA, foot problems also include peripheral arthritis, dactylitis and enthesitis, particularly at the Achilles tendon, plantar fascia and tibialis posterior tendon insertions but also at many other sites. In PsA specifically, forefoot deformity affects over 90% of people with the condition, while almost two-thirds experience foot pain [12].

Other extra-articular features of IA can manifest in the foot, including peripheral neuropathy and entrapment neuropathies. The risk of peripheral arterial disease is also increased in IA, particularly amongst individuals with a history of steroid use [13]. Long-term steroid use can also contribute to poor tissue viability in the foot, and when combined with joint deformity and poor vascular supply, the risk of tissue breakdown is significantly increased. Foot ulcers are common in IA [14, 15], and in immunosuppressed patients these carry an increased risk of potentially serious infection.

Despite significant advances in the pharmacological management of IA with the advent of whole new classes of medication and a new treatment paradigm, foot problems persist. The impact of foot damage in IA is often underestimated [16] and trivialized, yet people with foot problems consistently report marked reduction in their quality of life, indicating that the impact of foot disorders extends well beyond localized pain and discomfort [17].

Current practice

A person with IA might present to primary or secondary care with foot problems. In some cases, foot problems precede the diagnosis of IA; 31% of cases are known to have had their first IA symptoms in their feet [18]. After diagnosis, foot problems may be monitored as part of the assessment of overall prognosis and disease activity, potentially with follow-up imaging. Some units run multidisciplinary clinics, but more commonly people with foot problems are seen separately by rheumatology and podiatry, sometimes with additional input from physiotherapy, orthotics, occupational therapy or orthopaedic surgery. The presentation of foot problems in IA is diverse, with some people experiencing problems with general nail and skin care, whereas others have pain and change in foot shape and posture (deformity), making it difficult to walk and find suitable footwear. Such problems can have specific challenges for children and young people as their musculoskeletal system is growing and developing. Others may present with neurological or vascular disease affecting the feet, or with foot ulcers. Treatments for foot pain and deformity can include general nail care, callus debridement, foot orthoses, footwear advice and provision, stretching and strengthening exercises, lifestyle advice and surgery. People with persistent active inflammation in the foot may benefit from corticosteroid injections or a change in systemic treatment.

Variation in practice is widespread and the inadequacies of foot care in the UK are well documented. Although National Early Inflammatory Arthritis Audit (NEIAA) data indicated that 76% of rheumatology departments had podiatry access in 2020 [19], a 2021 BSR rheumatology workforce report highlighted that 80% of departments do not have a podiatrist embedded in their multidisciplinary team [20]. Additionally, a recent clinical audit into the adherence of foot health management standards of RA across six National Health Service

Downloaded from https://academic.oup.com/rheumatology/article/61/10/3907/6619581 by guest on 03 February 2023

(NHS) Trusts found that only one podiatry department had the facility to see people with RA within six weeks of their initial diagnosis [21], while cross-sectional and longitudinal cohort studies in secondary care frequently report that only 30% to 40% of people with RA access any form of professional foot care or surgery [22–24].

It has been suggested that better integration of foot health services into rheumatology would be beneficial for people with IA [25]. Referral pathways are often unclear, and the lack of podiatrists within specialist teams means many patients seek foot care from the independent sector or non-specialist podiatrists who may not have the specific knowledge to manage their problems. Poor compliance with current foot health standards amongst podiatry departments is prevalent [21].

2 Who the guideline is for

This guideline is for

- rheumatologists, general practitioners, orthopaedic surgeons, allied health professionals, and specialist rheumatology nurses involved in the management of people with foot problems in IA;
- people with foot problems in IA and their carers.

Equality considerations

- none known.

3 What the guideline will cover

3.1 Who is the focus?

Groups that will be covered

- Adults with IA affecting the foot;
- Children and young people with IA affecting the foot.

3.2 Settings

Settings that will be covered

- Primary care and community settings;
- Secondary and tertiary care settings.

3.3 Activities, services or aspects of care

Key areas that will be covered

We will look at evidence in the areas below when developing the guideline, but it may not be possible to make recommendations in all the areas.

Treatment of people

Foot problems (including pain, deformity, nail and skin pathologies, ulceration, reduced circulation and neuropathy) in people with the following rheumatic diseases:

- RA;
- SpA, including PsA, AS, enteropathic arthritis, reactive arthritis and undifferentiated SpA;
- JIA.

Assessment and diagnosis

- Assessments;
- Imaging;
- Referral to specialist foot services.

Treatment strategy

- personalized care;
- orthotic devices;
- footwear;
- targeted exercises and gait rehabilitation;
- nail and skin care;
- wound management;
- targeted injection therapy;
- reviewing systemic disease control;
- surgical referral;
- follow-up and monitoring.

Secondary prevention

- physical activity;
- smoking;
- weight loss.

Areas that will not be covered

- Surgical procedures;
- Treatment of traumatic foot injuries;
- Systemic drug therapy.

Related guidance

3.4 Key issues and draft questions

While writing this scope, we have identified the following key issues and draft questions related to them. The key issues and draft questions will be used to develop more detailed review questions, which guide the systematic review of the literature.

Assessment and diagnosis

Assessments

1. In adults or children and young people with suspected or confirmed IA, what clinical assessments should be undertaken when assessing foot health and disease activity, and how often?

Imaging

2. In adults or children and young people with suspected or confirmed IA, what imaging should be requested

Downloaded from https://academic.oup.com/rheumatology/article/61/10/3907/6619581 by guest on 03 February 2023

when assessing foot health, and when should imaging be requested?

Referral to specialist foot services

3. When should adults or children and young people with suspected or confirmed IA be referred to specialist foot services, e.g. podiatry?

Treatment strategy

Personalised care

4. In adults or children and young people with foot problems in IA, what personalised care (e.g. support for self-management, activation, shared decision making and culturally-sensitive education) relating to foot health, and considering a person's wider biopsychosocial health determinants, should be provided and when?

Orthotic devices

5. In adults or children and young people with foot problems in IA, are orthotic devices effective, when are they indicated, and which types of orthotic devices are effective?

Footwear

6. In adults or children and young people with foot problems in IA, what types of footwear are effective?

Targeted exercises, gait rehabilitation and electrophysical therapies

7. In adults or children and young people with foot problems in IA, what frequency, intensity, type and time (duration) of exercises, gait rehabilitation and electrophysical therapies is effective?

Nail and skin care

8. In adults or children and young people with common toenail pathologies in IA, what conservative treatments are effective, and when should abnormal nails be surgically removed?
9. In adults or children and young people with common skin pathologies (e.g. callus) in IA, what treatments are effective?

Wound management

10. In adults or children and young people with foot ulceration in IA, including infected foot ulcers, what treatments are effective?

Targeted injection therapy

11. In adults or children and young people with foot problems in IA, are local corticosteroid injections safe and effective, and if so, when should these be offered?

Reviewing systemic disease control

12. When should local foot symptoms prompt a review of systemic disease control in adults or children and young people with IA?

Surgical referral

13. In adults or children and young people with foot problems in IA, when should a surgical referral be considered?
14. In patients requiring foot and ankle surgical procedures, including nail surgery, should biologics/DMARDs be stopped, when should they be stopped, and for how long?

Follow-up and monitoring

15. How often should foot health be reassessed in adults or children and young people with IA?
16. In young people with IA who are transitioning from paediatric to adult care, how should foot health be incorporated?

Secondary prevention

Physical activity

17. In adults or children and young people with foot problems in IA, what is the clinical effectiveness of physical activity?

Smoking

18. In adults or children and young people with foot problems in IA who smoke, what is the clinical effectiveness of giving up smoking?

Weight loss

19. In adults or children and young people with foot problems in IA who are overweight or obese, what is the clinical effectiveness of weight loss?

The guideline is expected to be published in 2023.

4 Guideline working group constituency

Edward Roddy (WG lead) – Rheumatologist
Mike Backhouse (WG deputy lead) – Podiatrist
Lara Chapman (lead author) – Podiatrist
Louise Warburton – GP
Jasmine Davey – Lay member
Alan Rawlings – Lay member
Susan Varley – Lay member
Adele Whitgreave – Lay member
Adam Lomax – Orthopaedic foot/ankle surgeon
Rob Rees – Orthopaedic foot/ankle surgeon
Robbie Rooney – Orthotist
Rachel Ferguson – Paediatric Podiatrist
Gavin Cleary – Paediatric Rheumatologist
Lindsay Bearne – Physiotherapist
Lindsey Cherry – Podiatrist
Helen McKeeman – Podiatrist
Lucy Saunders – Podiatrist
Heidi Siddle – Podiatrist
Jim Woodburn – Podiatrist
Philip Helliwell – Rheumatologist
Sarah Ryan – Rheumatology nurse

2022 American College of Rheumatology/European Alliance of Associations for Rheumatology Classification Criteria for Eosinophilic Granulomatosis With Polyangiitis

Peter C. Grayson,[1] Cristina Ponte,[2] Ravi Suppiah,[3] Joanna C. Robson,[4] Anthea Craven,[5] Andrew Judge,[6] Sara Khalid,[5] Andrew Hutchings,[7] Raashid A. Luqmani,[5] Richard A. Watts,[8] and Peter A. Merkel[9]

This criteria set has been approved by the American College of Rheumatology (ACR) Board of Directors and the European Alliance of Associations for Rheumatology (EULAR) Executive Committee. This signifies that the criteria set has been quantitatively validated using patient data, and it has undergone validation based on an independent data set. All ACR/EULAR-approved criteria sets are expected to undergo intermittent updates.

The ACR is an independent, professional, medical and scientific society that does not guarantee, warrant, or endorse any commercial product or service.

Objective. To develop and validate revised classification criteria for eosinophilic granulomatosis with polyangiitis (EGPA).

Methods. Patients with vasculitis or comparator diseases were recruited into an international cohort. The study proceeded in 5 phases: 1) identification of candidate criteria items using consensus methodology, 2) prospective collection of candidate items present at the time of diagnosis, 3) data-driven reduction of the number of candidate items, 4) expert panel review of cases to define the reference diagnosis, and 5) derivation of a points-based risk score for disease classification in a development set using least absolute shrinkage and selection operator logistic regression, with subsequent validation of performance characteristics in an independent set of cases and comparators.

Results. The development set for EGPA consisted of 107 cases of EGPA and 450 comparators. The validation set consisted of an additional 119 cases of EGPA and 437 comparators. From 91 candidate items, regression analysis identified 11 items for EPGA, 7 of which were retained. The final criteria and their weights were as follows: maximum eosinophil count ≥1 × 10^9/liter (+5), obstructive airway disease (+3), nasal polyps (+3), cytoplasmic antineutrophil cytoplasmic antibody (ANCA) or anti–proteinase 3 ANCA positivity (−3), extravascular eosinophilic predominant inflammation (+2), mononeuritis multiplex/motor neuropathy not due to radiculopathy (+1), and hematuria (−1). After excluding mimics of vasculitis, a patient with a diagnosis of small- or medium-vessel vasculitis could be classified as having EGPA if the cumulative score was ≥6 points. When these criteria were tested in the validation data set, the sensitivity was 85% (95% confidence interval [95% CI] 77–91%) and the specificity was 99% (95% CI 98–100%).

Conclusion. The 2022 American College of Rheumatology/European Alliance of Associations for Rheumatology classification criteria for EGPA demonstrate strong performance characteristics and are validated for use in research.

This article is published simultaneously in the March 2022 issue of *Annals of the Rheumatic Diseases*.

The Diagnostic and Classification Criteria in Vasculitis (DCVAS) study, of which the development of these classification criteria was a part, was funded by grants from the American College of Rheumatology (ACR), the European Alliance of Associations for Rheumatology (EULAR), the Vasculitis Foundation, and the University of Pennsylvania Vasculitis Center.

INTRODUCTION

Eosinophilic granulomatosis with polyangiitis (EGPA), formerly known as Churg-Strauss syndrome, is a form of vasculitis that is histologically defined by eosinophil-rich, necrotizing granulomatous inflammation primarily involving the respiratory tract, along with necrotizing vasculitis of small- to medium-sized arteries (1). EGPA is considered a form of antineutrophil cytoplasmic antibody (ANCA)–associated vasculitis (AAV), along with granulomatosis with polyangiitis (GPA) and microscopic polyangiitis (MPA). ANCAs are detected in ~40–60% of patients with EGPA and are typically directed against myeloperoxidase (MPO) (2,3).

In 1990, the American College of Rheumatology (ACR) published classification criteria for EGPA (4). By current standards, these criteria have never been validated because they were developed using data from only 20 patients with EGPA without independent test and validation sets. Furthermore, the criteria were derived by comparing clinical data from patients with EGPA to data from 787 patients with other forms of vasculitis. Many of these comparators were patients with giant cell arteritis, a form of large-vessel vasculitis that is typically not difficult to readily distinguish from EGPA based on obvious clinical differences. Despite these methodologic weaknesses, the 1990 ACR criteria for EGPA have existed unchanged for several decades and have been useful to advance clinical research in these diseases. This article outlines the development and validation of the new ACR/European Alliance of Associations for Rheumatology (EULAR)–endorsed classification criteria for EGPA.

METHODS

A detailed and complete description of the methods involved in the development and validation of the classification criteria for EGPA is provided in Supplementary Appendix 1, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41982/abstract. Briefly, an international Steering Committee comprising clinician investigators with expertise in vasculitis, statisticians, and data managers was established to oversee the overall Diagnostic and Classification Criteria in Vasculitis (DCVAS) project (5). The Steering Committee established a 5-stage plan using data-driven and consensus methodology to develop the criteria for each of 6 forms of vasculitis.

Stage 1: generation of candidate classification items for the systemic vasculitides. Candidate classification items were generated by expert opinion and reviewed by a group of vasculitis experts across a range of specialties using a nominal group technique.

Stage 2: DCVAS prospective observational study. A prospective, international, multisite observational study was conducted (see Appendix A for study investigators and sites). Ethical approval was obtained from national and local ethics committees. Consecutive patients representing the full spectrum of disease were recruited from academic and community practices. Patients were included if they were 18 years or older and had a diagnosis of vasculitis or a condition that mimics vasculitis. Patients with AAV could only be enrolled within 2 years of diagnosis. Only data present at diagnosis were recorded.

Stage 3: refinement of candidate items specifically for AAV. The Steering Committee conducted a data-driven process to reduce the number of candidate items of relevance to cases and comparators for AAV. Items were selected for exclusion if they had a prevalence of <5% within the data set and/or they were not clinically relevant for classification criteria (e.g., related to infection, malignancy, or demographic characteristics). Low-frequency items of clinical importance could be combined, when appropriate.

Stage 4: expert review to derive a gold standard–defined final set of cases of AAV. Experts in vasculitis from a wide range of geographic locations and specialties reviewed all submitted cases of vasculitis and a random subset of mimics of vasculitis. Each reviewer was asked to review ~50 submitted cases to confirm the diagnosis and to specify the certainty of their diagnosis as follows: very certain, moderately certain, uncertain, or very uncertain. Only cases agreed upon with at least moderate certainty were retained for further analysis.

Stage 5: derivation and validation of the final classification criteria for EGPA. The DCVAS AAV data set was randomly split into development (50%) and validation (50%) sets. Comparisons were performed between cases of EGPA and a comparator group randomly selected from the DCVAS cohort in the following proportions: another type of AAV (including GPA and MPA), 60%; another form of small-vessel vasculitis (e.g., cryoglobulinemic vasculitis) or medium-vessel

Luqmani, DM, FRCP, Rheumatology Department, Nuffield Orthopaedic Centre, University of Oxford, Windmill Road, Oxford OX3 7LD, UK (email: raashid.luqmani@ndorms.ox.ac.uk).

Submitted for publication February 28, 2020; accepted in revised form September 21, 2021.

vasculitis (e.g., polyarteritis nodosa), 40%. Least absolute shrinkage and selection operator (lasso) logistic regression was used to identify items from the data set and create a parsimonious model including only the most important items. The final items in the model were formulated into a clinical risk-scoring tool with each factor assigned a weight based on its respective regression coefficient. A threshold that best balanced sensitivity and specificity was identified for classification.

In sensitivity analyses, the final classification criteria were applied to an unselected population of cases and comparators from the DCVAS data set based on the submitting physician diagnosis. Comparison was also made between the measurement properties of the new classification criteria for EGPA and the 1990 ACR classification criteria for EGPA using pooled data from the development and validation sets.

RESULTS

Generation of candidate classification items for the systemic vasculitides. The Steering Committee identified >1,000 candidate items for the DCVAS case report form (see Supplementary Appendix 2, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41982/abstract).

DCVAS prospective observational study. Between January 2011 and December 2017, the DCVAS study recruited 6,991 participants from 136 sites in 32 countries. Information on the DCVAS sites, investigators, and participants is listed in Supplementary Appendices 3, 4, and 5, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41982/abstract.

Refinement of candidate items specifically for AAV. Following a data-driven and expert consensus process, 91 items from the DCVAS case report form were retained for regression analysis, including 45 clinical (14 composite), 18 laboratory (2 composite), 12 imaging (all composite), and 16 biopsy (1 composite) items. Some clinical items were removed in favor of similar but more specific pathophysiologic descriptors. For example, "Hearing loss or reduction" was removed, and the composite item "Conductive hearing loss/sensorineural hearing loss" was retained. See Supplementary Appendix 6, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41982/abstract, for the final candidate items used in the derivation of the classification criteria for GPA, MPA, and EGPA.

Expert review to derive a gold standard–defined final set of cases of AAV. Fifty-five independent experts reviewed vignettes derived from the case report forms for 2,871 cases submitted with a diagnosis of either small-vessel vasculitis (90% of case report forms) or another type of vasculitis or a mimic of vasculitis (10% of case report forms). The characteristics of the expert reviewers are shown in Supplementary Appendix 7, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41982/abstract. A flow chart showing the results of the expert review process is shown in Supplementary Appendix 8, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41982/abstract. A total of 2,072 cases (72%) passed the process and were designated as cases of vasculitis; these cases were used for the stage 5 analyses.

After expert panel review, 226 of 315 cases of EGPA were retained for subsequent analysis. Compared to patients who were retained, patients who were excluded from further analysis

Table 1. Demographic and disease features of cases of EGPA and comparators*

	EGPA (n = 226)	Comparators (n = 887)†	*P*
Age, mean ± SD years	52.9 ± 14.4	56.2 ± 17.6	0.009
Sex, no. (%) female	113 (50.0)	445 (50.2)	1.000
Maximum serum creatinine, mean ± SD			<0.001
μmoles/liter	85.0 ± 53.6	205.90 ± 237.0	
mg/dl	0.96 ± 0.6	2.33 ± 2.7	
cANCA positive, no. (%)	17 (7.5)	251 (28.3)	<0.001
pANCA positive, no. (%)	83 (36.7)	289 (32.6)	0.271
Anti–PR3-ANCA positive, no. (%)	7 (3.1)	264 (29.8)	<0.001
Anti–MPO-ANCA positive, no. (%)	98 (43.4)	323 (36.4)	0.065
Maximum eosinophil count ≥1 × 10^9/liter, no. (%)	208 (92.0)	53 (6.0)	<0.001

* cANCA = cytoplasmic antineutrophil cytoplasmic antibody; pANCA = perinuclear ANCA; anti–PR3-ANCA = anti–proteinase 3–ANCA; anti–MPO-ANCA = anti–myeloperoxidase-ANCA.
† Diagnoses of comparators for the classification criteria for eosinophilic granulomatosis with polyangiitis (EGPA) included granulomatosis with polyangiitis (n = 300), microscopic polyangiitis (n = 291), polyarteritis nodosa (n = 51), non–ANCA-associated small-vessel vasculitis that could not be subtyped (n = 51), Behçet's disease (n = 50), IgA vasculitis (n = 50), cryoglobulinemic vasculitis (n = 34), ANCA-associated vasculitis that could not be subtyped (n = 25), primary central nervous system vasculitis (n = 19), and anti–glomerular basement membrane disease (n = 16).

had significantly higher serum creatinine levels (mean ± SD 102.8 ± 88.7 versus 85.0 ± 53.6 μmoles/liter; $P = 0.03$), lower rates of MPO-ANCA positivity (22% versus 43%; $P < 0.01$), and were less likely to have maximum eosinophil counts ≥1 × 10^9/liter (62% versus 92%; $P < 0.01$). There were 887 comparators randomly selected for analysis. Table 1 shows the demographic and disease features of the 1,113 cases included in this analysis (226 patients with EGPA and 887 comparators), of which 557 (50%;107 patients with EGPA and 450 comparators) were in the development set, and 556 (50%; 119 patients with EGPA and 437 comparators) were in the validation set.

Derivation and validation of the final classification criteria for EGPA. Lasso regression of the previously selected 91 items yielded 11 independent items for EGPA (Supplementary Appendix 9A, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41982/abstract). Each item was then adjudicated by the DCVAS Steering Committee for inclusion based on clinical relevance and specificity to EGPA, resulting in 7 final items. Weighting of an individual criterion was based on logistic regression fitted to the 7 selected items (see Supplementary Appendix 10A, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41982/abstract).

Model performance. Use of a cutoff of ≥6 for total risk score (see Supplementary Appendix 11A, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41982/abstract, for different cut points) yielded a sensitivity of 84.9% (95% confidence interval [95% CI] 77.2–90.8%) and a specificity of 99.1% (95% CI 98.3–99.8%) in the validation set. The area under the curve (AUC) for the model was 0.98 (95% CI 0.97–1.00) in the development set and 0.99 (95% CI 0.97–1.00) in the validation set for the final EGPA classification criteria (Supplementary Appendix 12A, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41982/abstract).

2022 AMERICAN COLLEGE OF RHEUMATOLOGY / EUROPEAN ALLIANCE OF ASSOCIATIONS FOR RHEUMATOLOGY

CLASSIFICATION CRITERIA FOR EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS

CONSIDERATIONS WHEN APPLYING THESE CRITERIA

- **These classification criteria should be applied to classify a patient as having eosinophilic granulomatosis with polyangiitis when a diagnosis of small- or medium-vessel vasculitis has been made**
- **Alternate diagnoses mimicking vasculitis should be excluded prior to applying the criteria**

CLINICAL CRITERIA

Obstructive airway disease	+3
Nasal polyps	+3
Mononeuritis multiplex	+1

LABORATORY AND BIOPSY CRITERIA

Blood eosinophil count ≥ 1 x10^9/liter	+5
Extravascular eosinophilic-predominant inflammation on biopsy	+2
Positive test for cytoplasmic antineutrophil cytoplasmic antibodies (cANCA) or antiproteinase 3 (anti-PR3) antibodies	-3
Hematuria	-1

Sum the scores for 7 items, if present. A score of ≥ 6 is needed for classification of EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS.

Figure 1. 2022 American College of Rheumatology/European Alliance of Associations for Rheumatology classification criteria for eosinophilic granulomatosis with polyangiitis.

The final classification criteria for EGPA are presented in Figure 1 (for the slide presentation version, see Supplementary Figure 1, available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41982/abstract).

Sensitivity analyses. The classification criteria for EGPA were applied to 2,871 patients in the DCVAS database using the original physician-submitted diagnosis (n = 315 EGPA and 2,556 randomly selected comparators). Use of the same cut point of ≥6 points for the classification of EGPA yielded a similar specificity of 99% but a lower sensitivity of 75%. This upheld the a priori hypothesis that specificity would remain unchanged but sensitivity would be reduced in a population of patients that included fewer clearcut diagnoses of EGPA (i.e., cases that did not pass expert panel review).

When the 1990 ACR classification criteria for EGPA were applied to the DCVAS data set, the criteria performed poorly due to low sensitivity (44%) but retained excellent specificity (99%), with an AUC of 0.72 (95% CI 0.68–0.75).

DISCUSSION

Presented here are the final 2022 ACR/EULAR EGPA classification criteria. A 5-stage approach has been used, underpinned by data from the multinational prospective DCVAS study and informed by expert review and consensus at each stage. The comparator group for developing and validating the criteria were patients with other forms of AAV and other small- and medium-vessel vasculitides, which are the clinical entities where discrimination from EGPA is difficult, but important. The new criteria for EGPA have excellent sensitivity and specificity and incorporate ANCA testing. The criteria were designed to have face and content validity for use in clinical trials and other research studies.

These criteria are validated and intended for the purpose of *classification* of vasculitis and are not appropriate for use in establishing a *diagnosis* of vasculitis. The aim of the classification criteria is to differentiate cases of EGPA from similar types of vasculitis in research settings. Therefore, the criteria should only be applied when a diagnosis of small- or medium-vessel vasculitis has been made and all potential "vasculitis mimics" have been excluded. The exclusion of mimics is a key aspect of many classification criteria, including those for Sjögren's syndrome (6) and rheumatoid arthritis (7). The 1990 ACR classification criteria for vasculitis perform poorly when used for diagnosis (i.e., when used to differentiate between cases of vasculitis versus mimics without vasculitis) (8), and it is expected that the 2022 criteria would also perform poorly if used inappropriately as diagnostic criteria in people in whom alternative diagnoses, such as infection or other non-vasculitis inflammatory diseases, are still being considered. Specifically, the criteria were not developed to differentiate patients with EGPA from those with other related hypereosinophilic syndromes or eosinophilic malignancies (9).

The 2022 ACR/EULAR EGPA classification criteria reflect the collaborative effort of the international vasculitis community to delineate the salient clinical features that differentiate EGPA from other forms of vasculitis. The final criteria include 7 clinical items that are easily assessed during routine clinical evaluation of patients with EGPA. The criteria highlight the importance of blood eosinophilia, asthma, and eosinophilic inflammation to classify EGPA among other forms of vasculitis and specify additional features (e.g., nasal polyps, mononeuritis multiplex) that function as important disease classifiers. Classification criteria are intended to define a homogeneous group of patients with a particular disease for inclusion into clinical research studies. By maximizing specificity, the revised criteria for EGPA ensure that few cases will inappropriately meet the criteria threshold of ≥6 points; thus, these criteria will function to facilitate the conduct of future clinical trials and other studies in EGPA.

The negative items included in the final criteria underscore that these criteria are intended for use as classification, not diagnostic, criteria to differentiate EGPA from other forms of vasculitis in research settings. Both hematuria and anti–proteinase 3 ANCA (anti–PR3-ANCA) function as negative items in the new EGPA classification criteria, yet glomerulonephritis and ANCA are features of disease that, when present, can be useful to diagnose EGPA. When compared to other forms of AAV, however, biopsy-proven glomerulonephritis was significantly less common in the DCVAS cohort in patients with EGPA (4.9%) compared to those with GPA (27.8%) or MPA (48.5%). Similarly, anti–PR3-ANCAs have been reported in few patients with EGPA but are much more prevalent in GPA (10). For these reasons, hematuria and anti–PR3-ANCAs work against a patient with small-vessel vasculitis being classified as having EGPA. Although anti–MPO-ANCAs can be detected in 40–60% of patients with EGPA, anti–MPO-ANCA positivity was not included in the final criteria because these antibodies are significantly more prevalent in diseases like MPA and thus are not discriminant classifiers for EGPA (11).

There are some study limitations to consider. Although this was the largest international study ever conducted in vasculitis, most patients were recruited from Europe, Asia, and North America. The performance characteristics of the criteria should be further tested in African and South American populations, which may have different clinical presentations of vasculitis. These criteria were developed using data collected from adult patients with vasculitis. Although the clinical characteristics of EGPA and the other vasculitides which these criteria were tested against are not known to differ substantially between adults and children, these criteria should be applied to children with some caution. The scope of the criteria is intentionally narrow and applies only to patients who have been diagnosed as having vasculitis. Diagnostic criteria are not specified. The criteria are intended to identify homogeneous populations of disease and, therefore, may not be appropriate for studies focused on the full spectrum of clinical heterogeneity in these conditions. To maximize relevance and face

validity of the new criteria, study sites and expert reviewers were recruited from a broad range of countries and different medical specialties. Nonetheless, the majority of patients were recruited from academic rheumatology or nephrology units, which could have introduced referral bias.

There are several strengths to the new 2022 ACR/EULAR EGPA classification criteria. The criteria were developed within a large cohort reflecting international expertise in systemic vasculitis according to ACR guidance for classification criteria development (11). The criteria represent several important methodologic advancements compared to the original 1990 ACR classification criteria for EGPA. Expert review rather than submitting physician diagnosis was used as the diagnostic reference standard to minimize investigator bias. Second, while the 1990 ACR criteria were entirely derived in 20 patients with EGPA and not validated, the new criteria were developed in 107 patients with EGPA and validated in an independent test set that contained an additional 119 patients with EGPA. Third, unlike the 1990 ACR criteria, the new ACR/EULAR EGPA criteria are weighted to reflect the relative importance of specific items (e.g., eosinophil counts). Finally, when both criteria sets were tested within the DCVAS cohort, the performance characteristics of the 1990 ACR criteria were suboptimal when compared to the 2022 revised ACR/EULAR EGPA criteria.

The 2022 ACR/EULAR classification criteria for EGPA are the product of a rigorous methodologic process that utilized an extensive data set generated by the work of a remarkable international group of collaborators. These criteria have been endorsed by the ACR and EULAR and are now ready for use to differentiate one type of vasculitis from another to define populations in research studies.

ACKNOWLEDGMENTS

We acknowledge the patients and clinicians who provided data to the DCVAS project.

AUTHOR CONTRIBUTIONS

All authors were involved in drafting the article or revising it critically for important intellectual content, and all authors approved the final version to be published. Dr. Merkel had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

A Proposed Revision to the ACR20: The Hybrid Measure of American College of Rheumatology Response

AMERICAN COLLEGE OF RHEUMATOLOGY COMMITTEE TO REEVALUATE IMPROVEMENT CRITERIA

Objective. **Although use of the American College of Rheumatology 20% improvement criteria (ACR20) has standardized response measurement in rheumatoid arthritis (RA) trials, the ACR20 has been criticized as less sensitive to change than are continuous measures of response, and its threshold for response (≥20%) is thought to be low. Our goal was to redefine response in RA in a manner that 1) corresponds to a clinical impression of response (clinical validity), 2) maximizes sensitivity to change, and 3) allows for calculation of the ACR20 to continue standardization of reporting.**

Methods. **We examined multiple different ways of defining response, including dichotomous definitions (patient improved versus not improved), ordinal definitions (degree of response scored on an ordinal scale), disease activity indexes, continuous definitions, and definitions that were hybrids of continuous and ordinal measures. Candidate definitions included the ACR20, ACR50, ACR70, the Disease Activity Score, the Simplified Disease Activity Index, the ACR-N, the nACR, and the European League Against Rheumatism (EULAR) response. We also tested variations on these approaches. To test clinical validity, we administered a survey involving patients from a previous trial who had various levels of improvement and asked rheumatologists whether and by how much these patients improved. To determine sensitivity to change, we collected data from 11 large multicenter trials of disease-modifying antirheumatic drugs (DMARDs) in RA comprising 3,665 patients (7 anti–tumor necrosis factor α arms, 4 conventional DMARD arms, 2 biologic arms) and ranked candidate definitions of response according to their average *P* value across trials in distinguishing active treatment from placebo or combination therapy versus single-drug therapy.**

Results. **All 135 tested measures had clinical validity based on survey responses, although dichotomous measures did not capture the range of responses (e.g., the ACR20 did not capture the extra clinical improvement between the ACR20 and the ACR50). In trial analyses, continuous measures had the best sensitivity to change. Among the best scoring measures was a hybrid measure that retained information on the ACR20, ACR50, and ACR70 and combined that with the mean percent improvement in core set measures. When comparing 2 treatments, this hybrid measure had an average *P* value much lower than that for the ACR20. If a trial needed 200 patients to have 80% power (2-sided $\alpha = 0.05$) to detect a difference between treatments if it used the ACR20, the same trial would need 108 patients if the hybrid measure were used.**

Conclusion. **We suggest use of a new hybrid measure of RA response that maximizes sensitivity to change, correlates well with rheumatologists' impressions of improvement, and preserves the ACR20.**

KEY WORDS. Rheumatoid arthritis; Trials; Outcome measures.

INTRODUCTION

Before the 1990s, reports of rheumatoid arthritis (RA) trials cited multiple primary outcomes, often with little overlap of measures from trial to trial. This made it nearly impossible to evaluate whether therapies that produced 1 or 2 positive outcomes actually demonstrated treatment effi-

Supported by grants from the American College of Rheumatology and by the NIH (grant AR-47785).

Members of the American College of Rheumatology Committee to Reevaluate Improvement Criteria in Rheumatoid Arthritis are as follows: David Felson, MD, Chair, Daniel Aletaha, MD, Jennifer Anderson, PhD, Joan Bathon, MD, Maarten Boers, MD, Claire Bombardier, MD, Hyon Choi, MD, Maxime Dougados, MD, Dan Furst, MD, Gary Koch, PhD, Robert Landewé, MD, Mike LaValley, PhD, Kaleb Michaud, PhD, Hal Paulus, MD, Theodore Pincus, MD, Jeffrey Siegel, MD, Lee Simon, MD, Josef Smolen, MD, Peter Tugwell, MD, Desiree van der Heijde, MD, Barbara White, MD, Fred Wolfe, MD, and Hui Xie, PhD.

Dr. Bombardier has received consulting fees (less than $10,00 each) from Abbott, Amgen, AstraZeneca, Bayer, Inc., Bristol-Myers Squibb Canada Company, Hoffmann-la Roche, Pfizer, Roche Products, Schering Canada, Solvay Pharma, and Wyeth-Ayerst Research, is a member of the Advisory Board and has received consulting fees (more than $10,000) for Merck & Company, and holds research grants

cacy; it also created a formidable barrier to the comparison of treatments. This situation changed with the development of the American College of Rheumatology (ACR) core set of disease activity measures (1,2). The core set required the inclusion of 7 clinical end points for all RA trials: swollen joint count, tender joint count, physician's assessment of disease activity, patient's assessment of disease activity, patient's assessment of pain, and patient's assessment of physical function, and levels of an acute-phase reactant (either the C-reactive protein [CRP] level or the erythrocyte sedimentation rate [ESR]). The core set measures still constituted 7 outcome measures, without a single primary measure.

In the early 1990s, an ACR committee used the core set to develop a single measure of improvement, the ACR preliminary criteria for improvement in RA (ACR20) (3). An ACR20 response was defined as at least 20% improvement in both the tender joint count and the swollen joint count and at least 20% improvement in 3 of the 5 other core set measures listed above.

Adoption of the ACR20 (and promulgation of a similar definition of improvement by the European League Against Rheumatism [EULAR]) (4) represented a substantial advance in measuring clinical responses in rheumatology. Trials almost immediately became standardized, with most using the ACR20 as their primary outcome measure. Investigators, appropriately or not, began to compare ACR20 response rates between therapies, and response measures were defined for other rheumatic diseases. The ACR20 also became the primary outcome used by the US Food and Drug Administration (FDA) to evaluate new treatments for RA. The ACR20 focused on improvement in individual patients rather than the mean improvement in groups of treated patients, permitting investigation of why the response to treatment of individual patients differed (5).

Widespread use of the ACR20 highlighted flaws that were not noted during its development. First, as therapies improved, 20% improvement seemed like a low bar, and trials began to incorporate other thresholds for improvement such as the ACR50 and the ACR70. Second, the ACR20 was a dichotomous measure of individual response (i.e., response was either present or absent). However, incorporating information about the relative improvement among patients in a trial would not only be more informative, it would also increase the sensitivity to change of the response definition, making it easier to compare treatments. Furthermore, although the ACR20 measure was used widely, it was not used consistently. Some studies required an ACR20 response only at the end of the trial, other studies used maximal improvement at any time during the trial, and still others prespecified an area under the curve approach to the ACR20. The diversity of ways in which the ACR20 was used led to problems comparing results between trials.

Of these concerns, the main one focused on the realization that the ACR20 measure was not as sensitive to change as other, more continuously defined measures of improvement (6). For example, the ACR-N (a continuous outcome defined by the percent improvement in either the tender joint count, the swollen joint count, or 5 other outcomes) was proposed as being an improvement of the ACR20 (7), as was a definition that simply counted the number of core set measures that improved by at least 20%, the nACR. Although each of these alternatives offered advantages and disadvantages to the ACR20, it became obvious that a revision to the ACR20, with attention to its sensitivity to change, was needed. Two emerging changes in RA trials further motivated a modification of the ACR20: 1) increasing difficulty recruiting patients for trials, requiring an outcome measure that would limit sample size requirements, and 2) the availability of many new effective treatments whose comparative efficacy would not be evaluable without a new, more precise measure.

Two other challenges accompanied revision of the ACR20. Because the ACR20 is widely known and has become a standard way of communicating response rates, any new measure should be built on the ACR20 as much as possible. Also, any new measure must correlate with clinicians' impressions of improvement. With all of these sometimes conflicting goals, we set about to reevaluate the definition of response in RA trials.

METHODS

The approach we used to reevaluate improvement criteria was as follows:

1. Identify potential candidate measures of response, trying to be as comprehensive as possible. We considered all commonly used or proposed measures plus variations of these.

from Abbott Laboratories, Schering Canada, Pfizer, and BMS. Dr. Bathon has received consulting fees and/or honoraria (less than $10,000 each) from Wyeth and Centocor, and has contracts with Amgen, Biogen-Idec, Bristol Myers, Roche, and Rinat. Dr. Choi has received grant support from TAP Pharmaceuticals and serves on advisory boards for TAP and Savient Pharmaceuticals. Dr. Simon is a consultant for AAI Pharma, Abbott, Affinergy, Astrazeneca, Abraxxis, Alpha Rx, Avanir, Nuvo/Dimethaid, Neopharm, Novartis, Pfizer, Plx Pharma, Hisamatsu, LAB Pharma, Dr Reddys, Biosense, Cerimon, Leerink Swann, Alimera, Nomura, Luxor, Paraexel, Nitec, Bayer, Combinatoryx, Rigel, Chelsea, Regeneron, Genelabs, Cypress, SNBL, Skyepharma, Solace, Puretchventures, Puretch Development, Whit Mountain Pharma, TAP, Cell Therapeutics, Omeros, Jazz, Schwarz, Proethic, Takeda, Teva, Zydus, Proprius, Savient, Alder, Cure, Cellegy, Chemocentryx, McKesson, Diobex, Sepracor, Purdue, Serono, Coley, Mediimune, Altea, Neuromed, Polymerix, Talagen, and Tigenix. Dr. Tugwell has received consulting fees from Abbott, Almirall, Astra Zeneca, Aventis, Berlex, Biomatrix, Bristol-Myers Squibb, Cadeuceus Group, Centocor, Dimedix, Dimethaid, Eli Lilly, Glaxo-Welcome, Glaxo Smith Kline, Hoechst Marion Roussel, Innovus, Johnson & Johnson, Lilly Research, Medicine Group, Medicus, Merck, Merck Frosst, Novartis, Novopharm, Ortho-McNeil, Pennside, Roche, Sandoz, Scios, Searle, and Wyeth Ayerst, and organizes a biannual outcome measures consensus meeting (Outcome Measures in Rheumatology [OMERACT]), which has received financial support from numerous pharmaceutical companies. Dr. White is a past employee of Amgen, owns stock in Amgen, and has stock options in Medimmune.

Submitted for publication August 30, 2006; accepted in revised form September 26, 2006.

2. Determine the clinical construct validity of candidate measures. We created a survey of "paper" patients from a large anti–tumor necrosis factor (anti-TNF) trial and asked rheumatologist respondents which patients in this trial had improved and by how much. We correlated survey responses on the degree of patient improvement with the amount of response determined by candidate measures.
3. Assess the discriminant validity of candidate measures. We collected raw data from a group of large multicenter randomized trials testing second-line drug therapy in RA. We used these data to evaluate the discriminant validity (sensitivity to change) of the candidate measures.
4. Select a set of response criteria using a combination of clinical construct validity, discriminant validity, and consensus by the committee.

Step 1. Identify candidate measure. Our goal in identifying candidate measures was to be as comprehensive as possible. If we did not propose a candidate measure, it could not be ultimately selected. We used several criteria to come up with measures. We identified all currently used or recommended measures of response or disease activity in RA, including widely known measures, such as the ACR20, the ACR50, the Disease Activity Score (DAS), the Simplified Disease Activity Index (SDAI), the ACR-N, and others (Table 1). Also, we allowed for variations on these measures. For example, because some of these measures, such as the ACR20, required improvement in both the tender joint count and the swollen joint count, one variation we tested was to define response without any requirement for joint count improvement. This was called an unweighted ACR20.

We also created candidates of response that counted the number of core set measures improving. One example was the nACR (not the ACR-N), in which, for each patient, the number of core set measures that improved by ≥20% was counted. For a patient in a trial, scores for the nACR range from 0 to 7. We also tested the n2ACR, in which, for each core set measure, a patient received a score of 1 if the measure improved by ≥20% and a score of 2 if the same measure improved by 50% or more. Using the n2ACR, a patient in a trial could have a score ranging from 0 to 14.

We tested continuous measures, including the average percent improvement in all core set measures, with average defined both as the mean and the median. Other variations on this approach were evaluated.

One of the factors that has compromised the sensitivity to change of the ACR20 (8) is the requirement for improvement in the tender/swollen joint count, yet joint count improvement appears to be necessary for rheumatologists to characterize a patient as having improved (9,10). Therefore, we tested other ways of weighting joint count improvement that might not compromise sensitivity. For example, for the nACR (see above), one could doubly weight joint count improvement (i.e., ≥20% improvement in the tender or swollen joint count was counted twice, so that the nACR double-weighted score ranged from 0 to 9). Other ways of weighting joint count improvement were done in the context of new response variables (Table 1).

We created continuous measures, ordinal measures (such as the nACR), measures based on indexes of ACR activity (such as the DAS), and dichotomous measures (such as the ACR20). We also created a hybrid definition of response. A hybrid definition combines elements of 2 approaches, in this case the ACR20/50/70 approach and the continuously measured mean change in core set measures. The value of the hybrid was constrained to be within the limits of the dichotomous measures (e.g., a patient achieving ACR20 improvement but not an ACR50 response would have a hybrid score between 20 and 50. The value between 20 and 50 was determined based on the average improvement in core set measures. If a patient met the ACR50 criteria but not the ACR70 criteria, his or her score was between 50 and 70. A score of 70 or higher was defined similarly.) We tested variations on this hybrid approach, including the unweighted ACR20, ACR50, and ACR70, approaches in which the mean change was allowed to include worsening, and other approaches in which the lower limit of the score (worsening) was limited to −100 to eliminate outliers (improvement is naturally limited to +100).

Ultimately, we tested 135 candidate measures of improvement, which are listed with each of their variations in Table 1. However, presenting numeric results for all candidates involves excessive tabular data presentation. In addition, the variations on a measure performed similarly to the measure itself. Therefore, although Table 1 shows all of the candidate measures tested, we present results only for selected measures of particular interest.

Step 2. Determine clinical construct validity: the survey. To evaluate whether a candidate definition of response in RA correlated with rheumatologists' impressions of whether the patient had improved, we created a survey consisting of profiles drawn from RA patients who were receiving active treatment in a randomized trial. For each patient, we provided the values for core set measures at baseline and after 6 months of therapy (see Figure 1 for an example of a "paper" patient from the survey and the questions posed to respondents). Also, in a column after the baseline and 6-month data, we provided the percent change in each of the core set measures. For each patient, survey respondents were asked whether the patient had improved, and if respondents determined that a patient had improved, they were asked whether it was a minimal improvement, major improvement, or whether the patient's disease had gone into remission.

The paper patients chosen for the survey were selected to test the range of improvements in core set measures that might characterize different levels of clinical improvement. We selected trial patients who met criteria for ACR 0%, 10%, 20% . . . 100% improvement and varied which core set measures improved.

To examine clinical construct validity, we used rheumatologist responses to create a 4-level responder for each paper patient: no improvement, definite but not major improvement, major improvement, and remission. Using Spearman's rank correlation coefficients, we evaluated the relationship of this ordinal measure of response with the degree of response derived from each candidate measure.

Step 3. Assess the discriminant validity of candidate measures: analysis of RA trials. We collected data from 11 large, multicenter, randomized RA trials carried out

Table 1. Candidate measures of response that were evaluated

Variable name	Variable definition
O'Brien test	Nonparametric test that chooses the optimal weight for each core set measure in each trial based on the variability of the measure's score during the trial (a gold standard, not suitable for a candidate measure, but a good benchmark for comparison)
O'Brien.abs	Sum of ranks of absolute changes (ac) in all 7 core measures, where ac = final − baseline for each measure
O'Brien%	Sum of ranks of percentage changes (pc) in all 7 core measures, where for each measure pc = final − baseline/baseline
O'Brien.symm%	Sum of ranks of symmetric percentage changes (spc) in all 7 core measures, where for each measure spc = final − baseline/final + baseline
Continuous definitions of improvement*	
Percent change measures (pc)	
MeanACR	Mean % improvement in the American College of Rheumatology (ACR) 7 core set measures
ACR-N	Minimum (% tender joint count [TJC], % swollen joint count [SJC], median of other 5)
Mean3ACR	Mean (% TJC, % SJC, mean of % for other 5)
MedianACR	Median of % changes in 7 core set measures
FifthACR	Fifth highest % change
ThirdACR	Third highest % change
MeanACR2	Mean of change is all core set measures/mean of all core set measures at baseline
MeanACR3	Mean of the change in each core set measure/square root of measure score at baseline
MedianACR2	Median of change is all core set measures/median of all core set measures at baseline
MeanACR_bd	Bounded version of MeanACR, restricting worsening scores for each of 7% changes to be −100%
Symmetric percentage change measures where spc = final value − baseline value/final value + baseline value	
Meanspc	Mean symmetric % improvement
Wmeanspc	Mean of 7 with symmetric % TJC and symmetric % SJC double weighted
Medianspc	Median of 7 symmetric % changes
Disease activity indexes	
%DAS	Percentage change on DAS (Disease Activity Score)
DDAS	Absolute change on DAS
SpcDAS	Symmetric percentage change of DAS
%SDAI	Percentage change on SDAI (Simplified Disease Activity Index, Smolen)
DSDAI	Absolute change on SDAI
ODAI	For each core set measure, create ordinal scale 1,2,3,4 and average them
%ODAI	Percentage change in ODAI
DODAI	Absolute change in ODAI
EULAR	European League Against Rheumatism (EULAR) response criteria, where 0 = no response, 1 = moderate response, 2 = good response
OSDAI	SDAI cut at 10, 20 (ordinal measure 0, 1, 2 values)
DCDAI	SDAI without C-reactive protein (CRP) absolute change
%CDAI	Percentage change in CDAI (SDAI without CRP)
Pcmean	(Mean of core set measures score at end − mean of measures at start)/(mean of measures at start)
Acmean	(Mean of core set measures score at end − mean of measures at start)
Spcmean	(Mean of core set measures score at end − mean of measures at start)/(mean of measures at start + mean of measures at end)
Pcmedian	Similar to pc mean but with median replacing mean everywhere
Acmedian	Similar to ac mean but with median replacing mean everywhere
Spcmedian	Similar to spc mean but with median replacing mean everywhere
Count definitions of improvement	
nACR	nACR (number of core set measures improved by ≥20%)
nACRw	Weighted by TJC and SJC, if TJC and SJC ≥20%, nACRw = nACR, else nACRw = 0
nACRdw	Double weight of TJC and SJC
nACR50, w50, dw50	Similar as nACR-type measurements, but threshold for improvement increased to 50%
nACR70, w70, dw70	Similar as above, but threshold for improvement increased to 70%

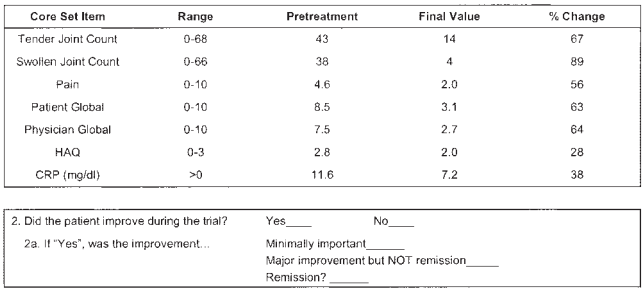
(continued)

Table 1. Candidate measures of response that were evaluated *(Continued)*

Variable name	Variable definition
n2ACR	nACR + nACR50
n2ACRw	nACRw + nACRw50
n2ACRdw	nACRdw + nACRdw50
n3ACR, w, dw	Similar as n2ACR-type measurements, but is a sum of nACR + nACR50 + nACR70 (or its variants)
Ordinal definitions of improvement	
ACRstep	0 if ACR20 = 0, 1 if ACR20 but not ACR50, 2 if ACR50 but not ACR70, 3 if ACR70
ACRuwstep	0 if not ACRuw20, 1 if ACRuw20 but not ACRuw50, 2 if ACRuw50 but not ACRuw70, 3 if ACRuw70
ACRd6wstep	0 if ACRd6w20 = 0, 1 if ACRd6w20 but not ACRd6w50, 2 if ACRd6w50 but not ACRd6w70, 3 if ACRd6w70
ACRd7wstep	0 if ACRd7w20 = 0, 1 if ACRd7w20 but not ACRd7w50, 2 if ACRd7w50 but not ACRd7w70, 3 if ACRd7w70
ACRstep3	Similar to ACRstep, but only with 20, 50 (as few achieve 70%)
ACRuwstep3	No 70%
ACRd6wstep3	No 70%
ACRd7wstep3	No 70%
Dichotomous measures of improvement	
ACR20, 30, 40, 50, 60, 70	The usual ACR20. Also tested ACR 30, 40, etc. each as dichotomous
ACRUW20, 30, 40, 50, 60, 70	ACR unweighted
ACRd6w20, 50, 70	ACR with joint counts double weighted (6 out of 9 = response)
ACRd7w20, 50, 70	ACR with joint counts double weighted (7 out of 9 = response)
MeanACR20, 30, 50	MeanACR ≥20%, 30%, 50%
SumACR-N4, 5, 6	SumACR-N ≥4, 5, 6
MedianACR20, 30, 40, 50, 60, 70	MedianACR ≥20%, 30%, 40%, 50%, 60%, 70%
MeanwACR20, 30, 40, 50, 60, 70	MeanwACR ≥20%, 30%, 40%, 50%, 60%, 70%
FifthACR20, 30, 50	FifthACR ≥20%, 30%, 50%
ThirdACR20, 30, 50	ThirdACR ≥20%, 30%, 50%
DASimp	DAS improvement (dichotomous)
LDAS1	Low disease activity based on DAS28
LDAS2	Low disease activity based on core set measurements
Hybrid definitions	
ACRhybrid	Hybrid definition: the cutoff is 20, 50, 70 based on ACR20, 50, 70; minimum (0, meanACR) if ACRstep = 0, maximum (0.2, minimum [0.5, meanACR]) if ACRstep = 1, maximum (0.5, minimum [0.7, meanACR]) if ACRstep = 2, maximum (0.7, meanACR) if ACRstep = 3
bdACRhybrid	Same as ACRhybrid but a bounded version. Replace meanACR with mean ACR_bd everywhere

* Percent change and symmetric percent change measures shown. Also tested were measures determined by absolute and not percent change (e.g., ameanACR = mean of actual changes in each core set measure).

since publication of the ACR20. Individual patient data were provided to investigators of the ACR subcommittee, with the goal of reevaluating the ACR20. Among the trials were placebo-controlled trials of disease-modifying anti-rheumatic drugs (DMARDs), different TNFα inhibitors, and a non–TNF-inhibiting biologic agent. We also obtained data from one comparative trial of a combination of agents versus a single agent. In most but not all trials, only 80% of the patient data were provided, with these patients selected at random; in the other trials, all patient data were provided. Based on agreement with sponsors providing the data, we have not provided identifiable trial information.



Core Set Item	Range	Pretreatment	Final Value	% Change
Tender Joint Count	0-68	43	14	67
Swollen Joint Count	0-66	38	4	89
Pain	0-10	4.6	2.0	56
Patient Global	0-10	8.5	3.1	63
Physician Global	0-10	7.5	2.7	64
HAQ	0-3	2.8	2.0	28
CRP (mg/dl)	>0	11.6	7.2	38

2. Did the patient improve during the trial? Yes____ No____

2a. If "Yes", was the improvement... Minimally important_____
Major improvement but NOT remission_____
Remission? _____

Figure 1. Example of a paper patient from the survey and example of the questions posed to respondents. HAQ = Health Assessment Questionnaire; CRP = C-reactive protein level.

We were prepared to exclude trials with ≥40% loss to followup, but no trial had this much loss. To analyze the data, we conducted intent-to-treat analyses using a last observation carried forward approach, preferentially selecting the 6-month outcome data when available. CRP was used as the acute-phase reactant when available, and the ESR was used if the CRP values were not available. Within each trial, we tested each candidate measure of response, focusing on the *P* value differentiating change

during active treatment versus change during placebo treatment, using Wilcoxon's rank sum test. For comparative trials, our *P* value was for the change in the combination-therapy arm versus that in the monotherapy arm. We defined this *P* value as our measure of discriminant validity.

In addition to the candidate measures of response tested, we added what we considered to be "gold standard" methods of differentiating treatments, variations on the O'Brien test, a nonparametric approach to comparing 2 groups assessed with multiple end points, which maximizes the discrimination between these groups and therefore the statistical difference between them (6). This test does not generate a response rate but compares treatments in terms of the percent improvement in each core set measure in each patient. This is not a measure that could be standardized across trials.

Step 4. Committee evaluation of data. First, an ACR subcommittee (the Committee to Reevaluate Improvement Criteria) and then the parent ACR Subcommittee on Classification and Response Criteria met to review preliminary results of the data analysis and survey. Based on advice from our statistical team, we focused on the leading 10–15 candidates, because it was likely that sensitivity to change dropped off substantially after that. Second, the parent committee and representatives of the FDA raised concerns that a joint count response was a necessary element of response definition. Thus, if they performed well, candidate measures that required or weighted the joint count response were considered preferable. Last, individual members of all committees emphasized the need to preserve the ACR20 in some manner.

RESULTS

Clinical construct validity: the survey. The survey was completed by 51 rheumatologists, mostly those attending the 2004 OMERACT (Outcome Measures in Rheumatology Clinical Trials) 7 meeting (Asilomar, CA), at which the survey was administered. Respondents included rheumatologists from the US, Canada, Australia, and several European countries. Of these, 2 had unusable data because too many responses were left blank. Examining the correlations of candidate measures of response with rheumatologists' impressions of the degree of improvement among paper patients (Table 2), we found that all correlated moderately well. The measures that performed poorly were primarily (but not exclusively) those that defined response in a dichotomous manner, such as the ACR70 or the DAS. This was because the range of improvement was not sampled by these dichotomous measures. For example, if a given patient had experienced major improvement or remission, the ACR20, a dichotomous measure, would label them only as improved and would not accurately characterize their more substantial improvement. Because of this limitation, dichotomous measures tended to have lower correlations (r values) with the range of patient improvement compared with ordinal measures, continuous measures, or measures that used an index approach to define response.

Table 2. Spearman's rank correlation coefficients (ranked from strongest to weakest) of mean survey response with candidate measure-defined response*

Discriminant validity: trial data. We turned to analysis of RA trial data, displaying candidates in order of the most sensitive to change to the least sensitive to change (Table 3). For each candidate measure, we produced an average rank of its sensitivity to change compared with all other candidate measures (average rank) and a weighted average rank that weights each trial by its study size. The minimum/maximum rankings range from 1 to 135, because we tested a total of 135 candidate measures, although (because of space limitations) we show only measures of interest. The measure with the greatest sensitivity to change was a

data-driven measure designed to be our gold standard, based on the O'Brien test.

The top scoring measures were those that counted the number of core set measures that improved by 20%, 50%, and 70%. This group of measures includes the n3ACR and the n3ACRdw (doubly weighted for joint count). The n3ACR definitions characterize a patient as having improved by 20%, 50%, or 70% in each of the core set measures, in which they would get, respectively, a score of 1, 2, or 3 for that core set measure. The n3ACR count for a given patient would range from 0 to 21, with a score of 21 being achieved if the patient had at least 70% improvement in all core set measures.

Next in the ranking of candidate measures was the hybrid measure, the bdACRhybrid. This measure combined the ACR20, ACR50, and ACR70 scores with a patient's mean improvement in core set measures. Because the patient in Figure 1 from the survey met the ACR50 criteria but not the ACR70 criteria, that patient had a bdACRhybrid score between 50 and 70. The patient's mean percent improvement in core set measures was 57.9, which is the bdACRhybrid score. The scores for other patients are presented in Appendix A.

The bdACRhybrid variable is limited to an overall score of −100 to +100. Given that when core set measures improve there is a drop in score, these measures cannot improve more than 100%, thereby setting an upper bound. This particular hybrid measure was also limited to −100 (maximal worsening). We tested unbounded versions of the hybrid, in which the score was allowed to decrease according to the mean percent worsening, but these hybrid versions were not as sensitive to change as the bounded version, perhaps because they permitted outlier values to have a greater effect.

When we examined other candidate measures of response, we found that their discriminant validity was less than that of the above-described measures (Table 3). These included commonly recommended measures, such as the EULAR criteria for improvement and the ACR-N. Dichotomous measures of improvement, such as the ACR20, were farther down the list, and the worst scoring measure tested was one of the measures of low disease activity. Both measures of low disease activity scored poorly, suggesting that low disease activity should not be used as a primary outcome measure in trials.

The difference between the best and the worst candidate scoring measures was substantial. For example, in a trial of conventional DMARDs, the worst scoring measures showed no significant difference between the efficacy of second-line drug and placebo, whereas the top scoring measures showed a significant difference between drug and placebo ($P < 0.001$). In general, the difference between the worst and the best groups of measures in terms of P values ranged from 10^{-3} to 10^{-6}, which represents a huge difference between the ability of the most and the least sensitive candidate measures to detect differences between therapies. Thus, the efficacy of some drugs versus placebo (or modest efficacy differences between 2 treatments) would not be detected if candidate measures at the bottom of the list were used. Our results also translate to smaller sample sizes needed in trials to detect the same treatment effects with statistical significance. For example, to achieve 80% power with a significance level of 0.05, a trial using the ACR20 would need 200 patients in order to detect a specific difference in treatments. Using the hybrid ACR response measure, only 108 patients would be needed to detect the same difference with the same power.

The committee considered data on the sensitivity to change of different candidate measures. Initially, because dichotomous measures had worse construct validity than did ordinal or continuous measures and were consistently among the worst performing candidate measures of response, these were rejected in our deliberations. We focused instead on the 10–15 measures that performed best. Additional concerns that were considered were understandability of the candidate measure, its compatibility with the ACR20, and its emphasis on joint count improvement without compromising sensitivity to change.

The options considered by the ACR committee and its parent committee included variations on the n3ACR and the bdACRhybrid. Because the other measures had worse sensitivity to change and did not preserve the ACR20/50/70 approach and/or they were not understandable, they were eliminated from consideration. Ultimately, the Committee to Reevaluate Improvement Criteria, working with the parent committee, selected the bdACRhybrid (which we will call the "hybrid ACR response measure") for the following reasons:

1. It was highly sensitive to change (ranked close to the top of all measures tested).
2. It incorporated a requirement for joint count improvement without compromising sensitivity to change.
3. It preserved the ACR20/50/70; the proportion of patients improving by these amounts is easily determined from data in which the bdACRhybrid is used.
4. It could be understood readily.

Scoring of the hybrid ACR response measure is shown in Table 4.

DISCUSSION

Using a data-driven consensus approach, a committee constituted by the ACR has revised the ACR definition of response and recommended a new hybrid measure that incorporates a patient-specific definition of improvement, allowing for the computation of ACR 20%, 50%, and 70% improvements, yet also incorporating a continuous measure of change. This measure addresses conflicting needs in defining improvement; that is, developing a measure that optimally detects modest differences between therapies, and retaining a standard measure that does not discard the widely used ACR20.

The hybrid ACR response measure is intended for use as an outcome measure in clinical trials. Its use enables modest treatment differences to be detected as statistically significant and allows trials to be carried out with fewer subjects than are required using current outcome measures.

Because drug developers may rely on this measure to perform smaller pivotal trials than are currently undertaken to gain FDA approval, use of the hybrid ACR re-

* Most widely clinically used measures and other representative results are presented. For definitions, see Table 1.
† Candidates of special interest.

sponse measure may make safety data less complete at the time of drug approval.

Disease activity states and response measures are not the same, and the former may be useful in clinical practice and even as a measure of the attained state in trials (e.g., low disease activity, remission). Our effort does not supplant

Table 4. Scoring method for the Hybrid American College of Rheumatology (ACR) response measure*

ACR status	Mean % change in core set measures			
	<20	≥20, <50	≥50, <70	≥70
Not ACR20	Mean % change	19.99	19.99	19.99
ACR20 but not ACR50	20	Mean % change	49.99	49.99
ACR50 but not ACR70	50	50	Mean % change	69.99
ACR70	70	70	70	Mean % change

* 1) Calculate the average percentage change in core set measures. For each core set measure, subtract score after treatment from baseline score and determine percentage improvement in each measure. Next, if a core set measure worsened by >100%, limit that percentage change to 100% (a − 100% bound). Then average the percentage changes for all core set measures. 2) Determine whether the patient has achieved: ACR20, ACR50, or ACR70. 3) Using the table above, obtain the Hybrid ACR response measure. To use the table, take the ACR20, ACR50, or ACR70 status of the patient (left column) and the mean percentage improvement in core set items; the Hybrid ACR score is where they intersect in the table.

valuable efforts by other groups of investigators to define different states of activity in RA, including low disease activity and remission. We do, however, suggest that the current definitions of low disease activity (and, by extension, remission) should not be used as primary outcome measures in trials, because they are among the least sensitive to change of the measures we evaluated. Our data also suggest that the available disease activity state measures do not perform as well in trials as does the new hybrid ACR response measure.

Our approach has some important limitations. First, we made several critical assumptions that affected our choice. We accepted the validity and high performance of the core set of outcome measures. Other core set measures might yield a different definition of response. Second, although our list of candidate measures was large, we may not have considered certain approaches that might have altered our decisions. Third, even with the assumptions, we may have produced a different answer using a different set of trial data, although our trials were large and varied enough that we suspect the ranking of candidate measures would not have changed much. Fourth, our candidate measures may rank slightly different if a different analytic approach (e.g., parametric analysis) were used, although in such an approach, outliers would be likely to compromise power to a greater extent.

Although requiring improvement in both the tender joint count and especially the swollen joint count can compromise the sensitivity to change of outcome measurement in RA, we believe there are creative solutions to this problem. We have proposed one solution, the hybrid ACR response measure, which requires improvement in the swollen and tender joint counts to reach a certain threshold score. Combined with the mean percent improvement in core set measures, one can derive the ACR hybrid measure score (see Table 4). To make it clear how this works, we provide additional tables in which we compute the new recommended response measure (see Appendix A).

We noted earlier that one major source of measurement heterogeneity in RA trials has been the varied ways in which the ACR20 has been defined. There are a variety of ways in which the hybrid ACR measure could be used based on timing of measurement. In another report, we shall propose an approach to timing of the hybrid ACR measure in trials so as to encourage more uniformity in measuring response in RA trials.

In summary, we suggest a revision to the ACR20 that creates a new hybrid outcome measure, a measure combining the ACR20, the ACR50, and the ACR70 and a continuous score of the mean improvement in core set measures. This new measure has much greater statistical power to distinguish the efficacy of treatments than do the currently recommended measures of response, including the ACR20.

AUTHOR CONTRIBUTIONS

Dr. Felson had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Study design. Felson, Xie, LaValley, Anderson, Furst, Boers, Pincus, Dougados, Bombardier, Simon.

Acquisition of data. Felson, Xie, Anderson, Wolfe, Furst, White.

Analysis and interpretation of data. Felson, Xie, LaValley, Anderson, Koch, Wolfe, Michaud, Furst, Boers, Bathon, Tugwell, Pincus, Dougados, van der Heijde, Smolen, Aletaha, Siegel, Choi, Paulus, White, Landewé, Simon.

APPENDIX A. AMERICAN COLLEGE OF RHEUMATOLOGY HYBRID SCORE OF 3 TRIAL PATIENTS

Patient 1. The patient did not meet the criteria for ACR20 (swollen joint count worsened). Therefore, the Hybrid ACR score must be <20, even though the mean change of all scores is 42.8. The Hybrid ACR score for this patient is 19.99.

Core set item	Range	Pretreatment	Final value	% change
Tender joint count	0–68	43	14	67
Swollen joint count	0–66	38	44	−16*
Pain	0–10	4.6	2.0	56
Patient global	0–10	8.5	3.1	63
Physician global	0–10	7.5	2.7	64
Health Assessment Questionnaire	0–3	2.8	2.0	28
C-reactive protein level (mg/dl)	>0	11.6	7.2	38

* Swollen joint count has worsened.

Patient 2. The patient met the criteria for ACR50 but not ACR70. Therefore, the Hybrid ACR score must be between 50 and 69.99. The mean percentage improvement is 73.29%. The ACR Hybrid score (limited by the failure of the patient to reach ACR70) is 69.99.

Core set item	Range	Pretreatment	Final value	% change
Tender joint count	0–68	43	14	67
Swollen joint count	0–66	38	14	63
Pain	0–10	4.6	1.0	78
Patient global	0–10	8.5	1.1	87
Physician global	0–10	7.5	2.7	64
Health Assessment Questionnaire	0–3	2.8	1.0	64
C-reactive protein level (mg/dl)	>0	11.6	1.2	90

Patient 3. The patient met the criteria for ACR50 but not ACR70. Therefore, the Hybrid ACR score must be between 50 and 69.99. The mean percentage change is 52.29, and the ACR Hybrid score is 52.29.

Core set item	Range	Pretreatment	Final value	% change
Tender joint count	0–68	43	14	67
Swollen joint count	0–66	38	19	50
Pain	0–10	4.6	2.0	56
Patient global	0–10	8.5	3.1	63
Physician global	0–10	7.5	2.7	64
Health Assessment Questionnaire	0–3	2.8	2.0	28
C-reactive protein level (mg/dl)	>0	11.6	7.2	38

AMERICAN COLLEGE of RHEUMATOLOGY
Empowering Rheumatology Professionals

American College of Rheumatology (ACR) Guideline for the Screening, Monitoring, and Treatment of Interstitial Lung Disease in People with Systemic Autoimmune Rheumatic Disease

Project Plan – August 2022

ORGANIZATIONAL LEADERSHIP AND SUPPORT

This project is led and funded by the American College of Rheumatology (ACR).

BACKGROUND

Interstitial lung disease (ILD), a heterogeneous group of disorders characterized by inflammation and fibrosis of the lung parenchyma, is a significant cause of morbidity and mortality in people with systemic autoimmune rheumatic diseases (ARDs). Although all people with ARDs are at risk for developing ILD, those with systemic sclerosis (SSc), rheumatoid arthritis (RA), mixed connective tissue disease (MCTD), polymyositis/dermatomyositis (PM/DM), and Sjogren's Syndrome (SS) are at the greatest risk (1,2) For example, ILD affects approximately 40-60% of adults with SSc and is the leading cause of death and hospitalization in this population (3-6).

Despite the life-threatening nature of ARD-ILD and the emerging potential of new therapies to arrest disease progression, there are no clinical practice guidelines for ILD screening or treatment in the ARDs. It is hypothesized that screening for ARD-ILD could lead to early interventions to prevent or slow progression of this often lethal disease. Hence, there is an urgent need to develop ARD-ILD screening, monitoring, and treatment guidelines.

OBJECTIVES

The objective of this project is to develop a clinical practice guideline that includes evidence-based consensus recommendations for clinicians who care for people with systemic autoimmune rheumatic disease who are at risk for or have been diagnosed with interstitial lung disease (ILD).

Specifically, we aim to:

1. Develop recommendations regarding optimal screening tests to screen for ILD in people with specific ARDs.
2. Develop recommendations for the monitoring of ARD-ILD (monitoring for both the development and progression of ARD-ILD).
3. Develop treatment recommendations for ARD-ILD.

THEMES OF PICO QUESTIONS

The PICO (Population/patients, Intervention, Comparator, and Outcomes; *see Appendix A*) questions developed for this guideline fall into 5 major categories:

American College of Rheumatology (ACR) Guideline for the Screening, Monitoring, and Treatment of Interstitial Lung Disease in People with Systemic Autoimmune Rheumatic Disease

Project Plan – August 2022

1. Screening for ILD in people with rheumatic disease at increased risk of developing ILD
2. Monitoring ILD progression and treatment complications
3. Treatment of ILD: first therapy
4. Treatment of ILD after ILD progression on first ILD therapy
5. Treatment of rapidly progressive ILD

METHODS

Identification of Studies

Literature search strategies, based on PICO questions, were drafted by a research librarian with input from the Core Team. Searches were performed in OVID Medline (1946 +), Embase (1974 +), and PubMed (mid-1960s +).

The search strategies were developed using the controlled vocabulary or thesauri language for each database: Medical Subject Headings (MeSH) for OVID Medline and PubMed; and Emtree terms for Embase. Text words were also used in OVID Medline, PubMed, and Embase.

Search Limits

Only English language articles will be retrieved.

Literature Search Update

Literature searches will be updated just before the voting panel meeting to ensure completeness.

Inclusion/Exclusion Criteria

Appendix A includes the project's PICO questions, which outline the defined patient population, interventions, comparators, and outcomes. *Appendix B* includes the list of inclusion/exclusion criteria.

Management of Studies and Data

References and abstracts will be imported into bibliographic management software (EndNote) (7), duplicates removed, and exported to Distiller SR, a web-based systematic review manager (8). Screening and data abstraction forms will be created in Distiller SR. Search results will be divided among reviewers, and two reviewers will screen each title/abstract, with disagreements at the title/abstract screening stage defaulting to inclusion for full manuscript review. Following the same dual review process, disagreements at the full manuscript screening stage will be discussed and adjudicated by the literature review leadership, if necessary.

Phases

1. A search for randomized controlled trials and observational studies will be performed to determine existing studies covering outcomes of interest.

2. Additionally, recently published systematic reviews covering outcomes of interest will also be sought and used for reference cross-checking.
3. Chosen studies will be quality-assessed using the Instrument to assess the Credibility of Effect Modification Analyses.
4. Subsequently, identified studies will be assessed using the RevMan (10) and GRADE Pro tools (11).

GRADE Methodology

GRADE methodology will be used in this project to grade available evidence and facilitate development of recommendations. The certainty in the evidence (also known as 'quality' of evidence) will be graded as high, moderate, low or very low. The recommendations will have a strength, strong or conditional, and a direction, as in favor of or against the intervention. The strength of recommendations will not depend solely on the certainty in the evidence, but also on patient preferences and values, and the weight between benefits and harms. A series of articles that describe the GRADE methodology can be found on the GRADE working group's website: www.gradeworkinggroup.org.

Data Analysis and Synthesis

The literature review team will analyze and synthesize data from included studies that address the PICO questions. An evidence profile, including a GRADE Summary of Findings table, will be prepared for each PICO question using Review Manager (RevMan) (10) and GRADEprofiler (GRADEpro) software (11). The Summary of Findings table contains the benefits and harms for each outcome across studies, the assumed and corresponding risk for comparators and interventions (95% CI), the absolute risk and relative effect (95% CI), the number of participants/number of studies, and the certainty in the evidence for each critical and important outcome (i.e., high, moderate, low or very low).

The evidence profile documents the overall certainty in the evidence for each critical and important outcome across studies and summarizes the rationale of the GRADE criteria for downgrading (risk of bias, inconsistency, indirectness, imprecision, and publication bias), or upgrading the certainty in a body of evidence (large magnitude of effect, dose-response gradient, and all plausible confounding that would reduce a demonstrated effect).

Development of Recommendation Statements

PICO questions will be revised into drafted recommendation statements. Using the GRADE Evidence Profiles and Summaries of Findings tables, the voting panel, consisting of 11 rheumatologists, 5 pulmonologists, 1 radiologist, and at least 2 patients with rheumatic disease-associated ILD (specifically, ILD associated with either systemic sclerosis, rheumatoid arthritis, mixed connective tissue disease, dermatomyositis, polymyositis, or Sjogren's syndrome), will consider the drafted recommendation statements in two stages. The first assessment will be done individually, and the results will be

anonymous; this vote will only be used to determine where consensus might or might not already exist and develop an agenda for a virtual voting panel meeting. At the virtual voting panel meeting, chaired by the principal investigators, the panelists will discuss the evidence in the context of their clinical experience and expertise to arrive at consensus on the final recommendations. The voting panel meeting discussions will be supported by the GRADE expert as well as the literature review leader, who will attend the meeting to provide details about the evidence, as requested. Voting panel discussions and decisions will also be informed by a separately convened patient panel, which will meet in the days before the voting panel meeting, to provide unique patient perspectives on the drafted recommendations based on their experiences and the available literature.

PLANNED APPENDICES (AT MINIMUM)

A. Final literature search strategies
B. Inclusion/exclusion criteria
C. GRADE evidence profiles and summary of findings tables for each PICO question

AUTHORSHIP

Authorship of the guideline will include co-principal investigators Sindhu R. Johnson, MD, PhD, and Elana J. Bernstein, MD, MSc; co-literature review leaders Ilya Ivlev, MD, PhD, MBI and Stacey Uhl; MS content experts Marcy B. Bolster, MD, Jonathan H. Chung, MD, Sonye Danoff, MD, PhD, Michael George, MD, MSCE, and Dinesh Khanna, MD; and Gordon Guyatt, MD, GRADE expert, and Reza Mirza, MD, GRADE/Methodological Contributor. Members of the voting panel and literature review team will also be authors. The PIs will determine final authorship, dependent on the efforts made by individuals throughout the guideline development process, using international authorship standards as guidance.

DISCLOSURES/CONFLICTS OF INTEREST

The ACR's disclosure and COI policies for guideline development will be followed for this project. These can be found in the ACR Guideline Manual on this page of the ACR web site, under Policies & Procedures. *See Appendix D for participant disclosures.*

American College of Rheumatology (ACR) Guideline for the Screening, Monitoring, and Treatment of Interstitial Lung Disease in People with Systemic Autoimmune Rheumatic Disease

Project Plan – August 2022

ARDs included in this project

1. **Systemic sclerosis**
2. **Rheumatoid arthritis**
3. **Inflammatory myopathy**
4. **Sjogren's Syndrome**
5. **Mixed connective tissue disease**

SUMMARY OF PICO QUESTIONS

Screening PICO questions:

In people with ARD at increased risk of developing ILD, what is the impact of each of the following tests on diagnostic accuracy, disease-related outcomes, and diagnostic testing-related adverse events?

- PFTs vs. history/physical
- High resolution CT thorax vs. history/physical
- 6-minute walk test distance vs. history/physical
- Chest radiograph vs. history/physical
- Ambulatory desaturation vs. history/physical
- Chest radiograph vs. high resolution CT thorax
- PFTs vs. ambulatory desaturation
- High resolution CT thorax vs. PFTs
- High resolution CT thorax and PFTs vs. PFTs alone
- Bronchoscopy vs. no bronchoscopy
- Surgical lung biopsy vs. no surgical lung biopsy

Monitoring PICO questions:

In people with ARD who also have ILD, what is the impact of each of the following tests on responsiveness/sensitivity to change of the test, disease-related outcomes, treatment-related serious adverse events and testing-related adverse events?

- PFTs vs. history/physical
- High resolution CT thorax vs. history/physical
- 6-minute walk test distance vs. history/physical
- Chest radiograph vs. history/physical
- Ambulatory desaturation vs. history/physical
- Chest radiograph vs. high resolution CT thorax
- Bronchoscopy vs. no bronchoscopy

- High resolution CT thorax vs. bronchoscopy
- PFTs vs. 6-minute walk test distance
- PFTs and 6-minute walk test distance vs. PFTs alone
- PFTs vs. ambulatory desaturation
- PFTs and high resolution CT thorax vs. PFTs alone
- 6-minute walk test distance vs. ambulatory desaturation

Medical management – 1st ILD therapy PICO questions:

In people with ARD who also have ILD, what is the impact of each of the following therapies as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

- Mycophenolate vs. no mycophenolate
- Cyclophosphamide vs. no cyclophosphamide (I/V or oral)
- Leflunomide vs. no leflunomide
- Methotrexate vs. no methotrexate
- Azathioprine vs. no azathioprine
- Calcineurin inhibitors vs. no calcineurin inhibitors
- Anti-TNF therapy vs. no anti-TNF therapy
- Abatacept vs. no abatacept
- Anti-CD20 antibody vs. no anti-CD20 antibody
- IL-6 receptor antagonists vs. no IL-6 receptor antagonists
- JAK inhibitors vs. no JAK inhibitors
- Daily oral prednisone vs. no daily oral prednisone
- IV pulse glucocorticoids vs. no IV pulse glucocorticoids
- Nintedanib vs. no nintedanib
- Pirfenidone vs. no pirfenidone
- IVIG vs. no IVIG
- Plasma exchange vs. no plasma exchange
- Adding nintedanib to mycophenolate vs. not adding nintedanib to mycophenolate
- Adding pirfenidone to mycophenolate vs. not adding pirfenidone to mycophenolate
- Upfront combination of nintedanib with mycophenolate vs. mycophenolate alone
- Upfront combination of pirfenidone with mycophenolate vs. mycophenolate alone
- Methotrexate vs. mycophenolate
- Leflunomide vs. mycophenolate
- Azathioprine vs. mycophenolate
- I/V or oral cyclophosphamide vs. mycophenolate
- Calcineurin inhibitors vs. mycophenolate

- TNF inhibitors vs. mycophenolate
- IL-6 receptor antagonists vs. mycophenolate
- Anti-CD20 antibody vs. mycophenolate
- Abatacept vs. mycophenolate
- JAK inhibitors vs. mycophenolate
- Nintedanib vs. mycophenolate
- Pirfenidone vs. mycophenolate
- IVIG vs. mycophenolate
- Oral prednisone vs. mycophenolate
- Intravenous methylprednisolone vs. mycophenolate
- Plasma exchange vs. mycophenolate
- Methotrexate vs. anti-CD20 antibody
- Leflunomide vs. anti-CD20 antibody
- Azathioprine vs. anti-CD20 antibody
- I/V or oral cyclophosphamide vs. anti-CD20 antibody
- Calcineurin inhibitors vs. anti-CD20 antibody
- TNF inhibitors vs. anti-CD20 antibody
- IL-6 receptor antagonists vs. anti-CD20 antibody
- Abatacept vs. anti-CD20 antibody
- JAK inhibitors vs. anti-CD20 antibody
- Nintedinib vs. anti-CD20 antibody
- Pirfenidone vs. anti-CD20 antibody
- IVIG vs. anti-CD20 antibody
- Oral prednisone vs. anti-CD20 antibody
- Intravenous methylprednisolone vs. anti-CD20 antibody
- Plasma exchange vs. anti-CD20 antibody
- Methotrexate vs. azathioprine
- Leflunomide vs. azathioprine
- I/V or oral cyclophosphamide vs. azathioprine
- Calcineurin inhibitors vs. azathioprine
- TNF inhibitors vs. azathioprine
- IL-6 receptor antagonists vs. azathioprine
  Abatacept vs. azathioprine
- JAK inhibitors vs. azathioprine
- Nintedinib vs. azathioprine

- Pirfenidone vs. azathioprine
- IVIG vs. azathioprine
- Oral prednisone vs. azathioprine
- Intravenous methylprednisolone vs. azathioprine
- Plasma exchange vs. azathioprine
- Methotrexate vs. I/V or oral cyclophosphamide
- Leflunomide vs. I/V or oral cyclophosphamide
- Calcineurin inhibitors vs. I/V or oral cyclophosphamide
- TNF inhibitors vs. I/V or oral cyclophosphamide
- IL-6 receptor antagonists vs. I/V or oral cyclophosphamide
- Abatacept vs. I/V or oral cyclophosphamide
- JAK inhibitors vs. I/V or oral cyclophosphamide
- Nintedinib vs. I/V or oral cyclophosphamide
- Pirfenidone vs. I/V or oral cyclophosphamide
- IVIG vs. I/V or oral cyclophosphamide
- Oral prednisone vs. I/V or oral cyclophosphamide
- Intravenous methylprednisolone vs. I/V or oral cyclophosphamide
- Plasma exchange vs. I/V or oral cyclophosphamide
- Nintedanib vs. IL-6 receptor antagonists
- Referral for stem cell transplant vs. optimal medical management
- Referral for lung transplant vs. optimal medical management

Medical management – ILD progression on any 1st ILD therapy PICO questions

In ARD patients with ILD progression after 1st ILD therapy, what is the impact of adding each of the following therapies on disease-related outcomes and treatment-related adverse events?

- Combination of nintedanib and mycophenolate vs. mycophenolate alone
- Combination of pirfenidone and mycophenolate vs. mycophenolate alone
- Methotrexate vs. mycophenolate
- Leflunomide vs. mycophenolate
- Azathioprine vs. mycophenolate
- I/V or oral cyclophosphamide vs. mycophenolate
- Calcineurin inhibitors vs. mycophenolate
- TNF inhibitors vs. mycophenolate
- IL-6 receptor antagonists vs. mycophenolate
- Anti-CD20 antibody vs. mycophenolate
- Abatacept vs. mycophenolate

- JAK inhibitors vs. mycophenolate
- Nintedinib vs. mycophenolate
- Pirfenidone vs. mycophenolate
- IVIG vs. mycophenolate
- Oral prednisone vs. mycophenolate
- Intravenous methylprednisolone vs. mycophenolate
- Plasma exchange vs. mycophenolate
- Methotrexate vs. anti-CD20 antibody
- Leflunomide vs. anti-CD20 antibody
- Azathioprine vs. anti-CD20 antibody
- I/V or oral cyclophosphamide vs. anti-CD20 antibody
- Calcineurin inhibitors vs. anti-CD20 antibody
- TNF inhibitors vs. anti-CD20 antibody
- IL-6 receptor antagonists vs. anti-CD20 antibody
- Abatacept vs. anti-CD20 antibody
- JAK inhibitors vs. anti-CD20 antibody
- Nintedinib vs. anti-CD20 antibody
- Pirfenidone vs. anti-CD20 antibody
- IVIG vs. anti-CD20 antibody
- Oral prednisone vs. anti-CD20 antibody
- Intravenous methylprednisolone vs. anti-CD20 antibody
- Plasma exchange vs. anti-CD20 antibody
- Methotrexate vs. azathioprine
- Leflunomide vs. azathioprine
- I/V or oral cyclophosphamide vs. azathioprine
- Calcineurin inhibitors vs. azathioprine
- TNF inhibitors vs. azathioprine
- IL-6 receptor antagonists vs. azathioprine
- Abatacept vs. azathioprine
- JAK inhibitors vs. azathioprine
- Nintedinib vs. azathioprine
- Pirfenidone vs. azathioprine
- IVIG vs. azathioprine
- Oral prednisone vs. azathioprine
- Intravenous methylprednisolone vs. azathioprine

- Plasma exchange vs. azathioprine
- Methotrexate vs. I/V or oral cyclophosphamide
- Leflunomide vs. I/V or oral cyclophosphamide
- Calcineurin inhibitors vs. I/V or oral cyclophosphamide
- TNF inhibitors vs. I/V or oral cyclophosphamide
- IL-6 receptor antagonists vs. I/V or oral cyclophosphamide
- Abatacept vs. I/V or oral cyclophosphamide
- JAK inhibitors vs. I/V or oral cyclophosphamide
- Nintedinib vs. I/V or oral cyclophosphamide
- Pirfenidone vs. I/V or oral cyclophosphamide
- IVIG vs. I/V or oral cyclophosphamide
- Oral prednisone vs. I/V or oral cyclophosphamide
- Intravenous methylprednisolone vs. I/V or oral cyclophosphamide
- Plasma exchange vs. I/V or oral cyclophosphamide
- Referral for stem cell transplant vs. optimal medical management
- Referral for lung transplant vs. optimal medical management

Medical management – rapidly progressive ILD PICO questions

In ARD patients with rapidly progressive ILD, what is the impact of each of the following therapies as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

- Daily oral prednisone vs. no daily oral prednisone
- Pulse intravenous glucocorticoids vs. no pulse intravenous glucocorticoids
- Nintedanib vs. no nintedanib
- Pirfenidone vs. no pirfenidone
- Adding nintedanib to mycophenolate vs. not adding nintedanib to mycophenolate
- Adding pirfenidone to mycophenolate vs. not adding pirfenidone to mycophenolate
- Upfront combination of nintedanib with mycophenolate vs. mycophenolate alone
- Upfront combination of pirfenidone with mycophenolate vs. mycophenolate alone
- Methotrexate vs. mycophenolate
- Leflunomide vs. mycophenolate
- Azathioprine vs. mycophenolate
- I/V or oral cyclophosphamide vs. mycophenolate
- Calcineurin inhibitors vs. mycophenolate
- TNF inhibitors vs. mycophenolate
- IL-6 receptor antagonists vs. mycophenolate
- Anti-CD20 antibody vs. mycophenolate

- Abatacept vs. mycophenolate
- JAK inhibitors vs. mycophenolate
- Nintedinib vs. mycophenolate
- Pirfenidone vs. mycophenolate
- IVIG vs. mycophenolate
- Oral prednisone vs. mycophenolate
- Intravenous methylprednisolone vs. mycophenolate
- Plasma exchange vs. mycophenolate
- Methotrexate vs. anti-CD20 antibody
- Leflunomide vs. anti-CD20 antibody
- Azathioprine vs. anti-CD20 antibody
- I/V or oral cyclophosphamide vs. anti-CD20 antibody
- Calcineurin inhibitors vs. anti-CD20 antibody
- TNF inhibitors vs. anti-CD20 antibody
- IL-6 receptor antagonists vs. anti-CD20 antibody
- Abatacept vs. anti-CD20 antibody
- JAK inhibitors vs. anti-CD20 antibody
- Nintedinib vs. anti-CD20 antibody
- Pirfenidone vs. anti-CD20 antibody
- IVIG vs. anti-CD20 antibody
- Oral prednisone vs. anti-CD20 antibody
- Intravenous methylprednisolone vs. anti-CD20 antibody
- Plasma exchange vs. anti-CD20 antibody
- Methotrexate vs. azathioprine
- Leflunomide vs. azathioprine
- I/V or oral cyclophosphamide vs. azathioprine
- Calcineurin inhibitors vs. azathioprine
- TNF inhibitors vs. azathioprine
- IL-6 receptor antagonists vs. azathioprine
- Abatacept vs. azathioprine
- JAK inhibitors vs. azathioprine
- Nintedinib vs. azathioprine
- Pirfenidone vs. azathioprine
- IVIG vs. azathioprine
- Oral prednisone vs. azathioprine

- Intravenous methylprednisolone vs. azathioprine
- Plasma exchange vs. azathioprine
- Methotrexate vs. cyclophosphamide
- Leflunomide vs. cyclophosphamide
- Calcineurin inhibitors vs. I/V or oral cyclophosphamide
- TNF inhibitors vs. I/V or oral cyclophosphamide
- of IL-6 receptor antagonists vs. I/V or oral cyclophosphamide
- Abatacept vs. I/V or oral cyclophosphamide
- JAK inhibitors vs. I/V or oral cyclophosphamide
- Nintedinib vs. I/V or oral cyclophosphamide
- Pirfenidone vs. I/V or oral cyclophosphamide
- IVIG vs. I/V or oral cyclophosphamide
- Oral prednisone vs. I/V or oral cyclophosphamide
- Intravenous methylprednisolone vs. I/V or oral cyclophosphamide
- Plasma exchange vs. I/V or oral cyclophosphamide
- Dual combination therapy* vs. monotherapy†
- Triple combination therapy‡ vs. monotherapy†
- Triple combination therapy‡ vs. dual combination therapy*
- IVIG and/or plasma exchange in addition to monotherapy†, dual combination therapy*, or triple combination therapy‡ vs. monotherapy†, dual combination therapy*, or triple combination therapy‡ alone
- Antifibrotic (e.g., nintedanib or pirfenidone) in addition to monotherapy†, dual combination therapy*, or triple combination therapy‡ vs. monotherapy†, dual combination therapy*, or triple combination therapy‡ alone
- Referral for stem cell transplant vs. optimal medical management
- Referral for lung transplant vs. optimal medical management

APPENDIX A – PICO Questions

Screening for ILD in people with rheumatic disease at increased risk of developing ILD

1. In people with rheumatic disease at increased risk of developing ILD, what is the impact of pulmonary function tests (PFTs) compared to history/physical alone (e.g., shortness of breath (dyspnea), functional class and physical examination: crackles on auscultation) on diagnostic accuracy, disease-related outcomes, and diagnostic testing-related adverse events?

2. In people with rheumatic disease at increased risk of developing ILD, what is the impact of high resolution CT thorax compared to history/physical alone (e.g., shortness of breath (dyspnea), functional class and physical examination: crackles on auscultation) on diagnostic accuracy, disease-related outcomes, and diagnostic testing-related adverse events?

3. In people with rheumatic disease at increased risk of developing ILD, what is the impact of 6-minute walk test distance compared to history/physical alone (e.g., shortness of breath (dyspnea), functional class and physical examination: crackles on auscultation) on diagnostic accuracy, disease-related outcomes, and diagnostic testing-related adverse events?

4. In people with rheumatic disease at increased risk of developing ILD, what is the impact chest radiograph compared to history/physical alone (e.g., shortness of breath (dyspnea), functional class and physical examination: crackles on auscultation) on diagnostic accuracy, disease-related outcomes, and diagnostic testing-related adverse events?

5. In people with rheumatic disease at increased risk of developing ILD, what is the impact of ambulatory desaturation compared to history/physical alone (e.g., shortness of breath (dyspnea), functional class and physical examination: crackles on auscultation) on diagnostic accuracy, disease-related outcomes, and diagnostic testing-related adverse events?

6. In people with rheumatic disease at increased risk of developing ILD, what is the impact of chest radiograph compared to high resolution CT thorax on diagnostic accuracy, disease-related outcomes, and diagnostic testing-related adverse events?

7. In people with rheumatic disease at increased risk of developing ILD, what is the impact of pulmonary function tests (PFTs) compared to ambulatory desaturation on diagnostic accuracy, disease-related outcomes, and diagnostic testing-related adverse events?

8. In people with rheumatic disease at increased risk of developing ILD, what is the impact of high resolution CT thorax compared to PFTs on diagnostic accuracy, disease-related outcomes, and diagnostic testing-related adverse events?

9. In people with rheumatic disease at increased risk of developing ILD, what is the impact of high resolution CT thorax and PFTs compared to PFTs alone on diagnostic accuracy, disease-related outcomes, and diagnostic testing-related adverse events?

10. In people with rheumatic disease at increased risk of developing ILD, what is the impact of bronchoscopy (may include broncho-alveolar lavage, transbronchial biopsy, cryobiopsy) compared to no bronchoscopy (may include broncho-alveolar lavage, transbronchial biopsy, cryobiopsy) on diagnostic accuracy, disease-related outcomes, and diagnostic testing-related adverse events?

11. In people with rheumatic disease at increased risk of developing ILD, what is the impact of surgical lung biopsy compared to no surgical lung biopsy on diagnostic accuracy, disease-related outcomes, and diagnostic testing-related adverse events?

Monitoring disease progression and treatment complications

12. In people with rheumatic disease with ILD, what is the impact of pulmonary function tests (PFTs) compared to history/physical alone (e.g., shortness of breath (dyspnea), functional class and physical examination: crackles on auscultation) on responsiveness/sensitivity to change of the test, disease-related outcomes, treatment-related serious adverse events and testing-related adverse events?

13. In people with rheumatic disease with ILD, what is the impact of high resolution CT thorax compared to history/physical alone (e.g., shortness of breath (dyspnea), functional class and physical examination: crackles on auscultation) on responsiveness/sensitivity to change of the test, disease-related outcomes, treatment-related serious adverse events and testing-related adverse events?

14. In people with rheumatic disease with ILD, what is the impact of 6-minute walk test distance compared to history/physical alone (e.g., shortness of breath (dyspnea), functional class and physical examination: crackles on auscultation) on responsiveness/sensitivity to change of the test, disease-related outcomes, treatment-related serious adverse events and testing-related adverse events?

15. In people with rheumatic disease with ILD, what is the impact of chest radiograph compared to history/physical alone (e.g., shortness of breath (dyspnea), functional class and physical examination:

crackles on auscultation) on responsiveness/sensitivity to change of the test, disease-related outcomes, treatment-related serious adverse events and testing-related adverse events?

16. In people with rheumatic disease with ILD, what is the impact ambulatory desaturation compared to history/physical alone (e.g., shortness of breath (dyspnea), functional class and physician examination: crackles on auscultation) on responsiveness/sensitivity to change of the test, disease-related outcomes, treatment-related serious adverse events and testing-related adverse events?

17. In people with rheumatic disease with ILD, what is the impact of chest radiograph compared to high resolution CT thorax on diagnostic accuracy, disease-related outcomes, and diagnostic testing-related adverse events?

18. In people with rheumatic disease with ILD, what is the impact of bronchoscopy (may include broncho-alveolar lavage, transbronchial biopsy, cryobiopsy) compared to no bronchoscopy (may include broncho-alveolar lavage, transbronchial biopsy, cryobiopsy) on responsiveness/ sensitivity to change of the test, disease-related outcomes, treatment-related serious adverse events and testing-related adverse events?

19. In people with rheumatic disease with ILD, what is the impact of high resolution CT thorax compared to bronchoscopy (may include broncho-alveolar lavage, transbronchial biopsy, cryobiopsy) on responsiveness/ sensitivity to change of the test, disease-related outcomes, treatment-related serious adverse events and testing-related adverse events?

20. In people with rheumatic disease with ILD, what is the impact of PFTs compared to 6-minute walk test distance on responsiveness/ sensitivity to change of the test, disease-related outcomes, treatment-related serious adverse events and testing-related adverse events?

21. In people with rheumatic disease with ILD, what is the impact of PFTs and 6-minute walk test distance compared to PFTs alone on responsiveness/ sensitivity to change of the test, disease-related outcomes, treatment-related serious adverse events and testing-related adverse events?

22. In people with rheumatic disease with ILD, what is the impact of PFTs compared to ambulatory desaturation on responsiveness/ sensitivity to change of the test, disease-related outcomes, treatment-related serious adverse events and testing-related adverse events?

23. In people with rheumatic disease with ILD, what is the impact of PFTs and high resolution CT thorax compared to PFTs alone on responsiveness/ sensitivity to change of the test, disease-related outcomes, treatment-related serious adverse events and testing-related adverse events?

24. In people with rheumatic disease with ILD, what is the impact of 6-minute walk test distance compared to ambulatory desaturation on responsiveness/ sensitivity to change of the test, disease-related outcomes, treatment-related serious adverse events and testing-related adverse events?

Medical Management

Rheumatic disease 1st ILD therapy

25. In people with rheumatic disease with ILD, what is the impact of mycophenolate compared to no mycophenolate as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

26. In people with rheumatic disease with ILD, what is the impact of cyclophosphamide compared to no cyclophosphamide as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

27. In people with rheumatic disease with ILD, what is the impact of leflunomide compared to no leflunomide as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

28. In people with rheumatic disease with ILD, what is the impact of methotrexate compared to no methotrexate as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

29. In people with rheumatic disease with ILD, what is the impact of azathioprine compared to no azathioprine as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

30. In people with rheumatic disease with ILD, what is the impact of calcineurin inhibitors compared to no calcineurin inhibitors as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

31. In people with rheumatic disease with ILD, what is the impact of anti-TNF therapy compared to no anti-TNF therapy as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

32. In people with rheumatic disease with ILD, what is the impact of abatacept compared to no abatacept as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

33. In people with rheumatic disease with ILD, what is the impact of anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) compared to no anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

34. In people with rheumatic disease with ILD, what is the impact of IL-6 receptor antagonists (tocilizumab, sarilumab) compared to no IL-6 receptor antagonists (tocilizumab, sarilumab) as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

35. In people with rheumatic disease with ILD, what is the impact of JAK inhibitors compared to no JAK inhibitors as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

36. In people with rheumatic disease with ILD, what is the impact of daily oral prednisone compared to no daily oral prednisone as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

37. In people with rheumatic disease with ILD, what is the impact of IV pulse glucocorticoids compared to no IV pulse glucocorticoids first line ILD treatment on disease-related outcomes and treatment-related adverse events?

38. In people with rheumatic disease with ILD, what is the impact of nintedanib compared to no nintedanib as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

39. In people with rheumatic disease with ILD, what is the impact of pirfenidone compared to no pirfenidone as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

40. In people with rheumatic disease with ILD, what is the impact of IVIG compared to no IVIG as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

41. In people with rheumatic disease with ILD, what is the impact of plasma exchange compared to no plasma exchange as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

42. In people with rheumatic disease with ILD without ILD progression, what is the impact of adding nintedanib to mycophenolate compared to not adding nintedanib to mycophenolate on disease-related outcomes and treatment-related adverse events?

43. In people with rheumatic disease with ILD without ILD progression, what is the impact of adding pirfenidone to mycophenolate compared to not adding pirfenidone to mycophenolate on disease-related outcomes and treatment-related adverse events?

44. In people with rheumatic disease with ILD, what is the impact of upfront combination of nintedanib with mycophenolate compared to mycophenolate alone as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

45. In people with rheumatic disease with ILD, what is the impact of upfront combination of pirfenidone with mycophenolate compared to mycophenolate alone as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

46. In people with rheumatic disease with ILD, what is the impact of methotrexate compared to mycophenolate as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

47. In people with rheumatic disease with ILD, what is the impact of leflunomide compared to mycophenolate as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

48. In people with rheumatic disease with ILD, what is the impact of azathioprine compared to mycophenolate as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

49. In people with rheumatic disease with ILD, what is the impact of cyclophosphamide compared to mycophenolate as first line ILD treatment on disease-related outcomes and treatment-related adverse

events?

50. In people with rheumatic disease with ILD, what is the impact of calcineurin inhibitors compared to mycophenolate as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

51. In people with rheumatic disease with ILD, what is the impact of TNF inhibitors compared to mycophenolate as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

52. In people with rheumatic disease with ILD, what is the impact of IL-6 receptor antagonists (tocilizumab, sarilumab) compared to mycophenolate as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

53. In people with rheumatic disease with ILD, what is the impact of anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) compared to mycophenolate as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

54. In people with rheumatic disease with ILD, what is the impact of abatacept compared to mycophenolate as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

55. In people with rheumatic disease with ILD, what is the impact of JAK inhibitors compared to mycophenolate as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

56. In people with rheumatic disease with ILD, what is the impact of nintedinib compared to mycophenolate as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

57. In people with rheumatic disease with ILD, what is the impact of pirfenidone compared to mycophenolate as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

58. In people with rheumatic disease with ILD, what is the impact of IVIG compared to mycophenolate as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

59. In people with rheumatic disease with ILD, what is the impact of oral prednisone compared to mycophenolate as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

60. In people with rheumatic disease with ILD, what is the impact of intravenous methylprednisolone compared to mycophenolate as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

61. In people with rheumatic disease with ILD, what is the impact of plasma exchange compared to mycophenolate as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

62. In people with rheumatic disease with ILD, what is the impact of methotrexate compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

63. In people with rheumatic disease with ILD, what is the impact of leflunomide compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

64. In people with rheumatic disease with ILD, what is the impact of azathioprine compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

65. In people with rheumatic disease with ILD, what is the impact of cyclophosphamide compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

66. In people with rheumatic disease with ILD, what is the impact of calcineurin inhibitors compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

67. In people with rheumatic disease with ILD, what is the impact of TNF inhibitors compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

68. In people with rheumatic disease with ILD, what is the impact of IL-6 receptor antagonists (tocilizumab, sarilumab) compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

69. In people with rheumatic disease with ILD, what is the impact of abatacept compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

70. In people with rheumatic disease with ILD, what is the impact of JAK inhibitors compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

71. In people with rheumatic disease with ILD, what is the impact of nintedinib compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

72. In people with rheumatic disease with ILD, what is the impact of pirfenidone compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

73. In people with rheumatic disease with ILD, what is the impact of IVIG compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

74. In people with rheumatic disease with ILD, what is the impact of oral prednisone compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

75. In people with rheumatic disease with ILD, what is the impact of intravenous methylprednisolone compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

76. In people with rheumatic disease with ILD, what is the impact of plasma exchange compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

77. In people with rheumatic disease with ILD, what is the impact of methotrexate compared to azathioprine as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

78. In people with rheumatic disease with ILD, what is the impact of leflunomide compared to azathioprine as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

79. In people with rheumatic disease with ILD, what is the impact of cyclophosphamide compared to azathioprine as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

80. In people with rheumatic disease with ILD, what is the impact of calcineurin inhibitors compared to azathioprine as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

81. In people with rheumatic disease with ILD, what is the impact of TNF inhibitors compared to azathioprine as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

82. In people with rheumatic disease with ILD, what is the impact of IL-6 receptor antagonists (tocilizumab, sarilumab) compared to azathioprine as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

83. In people with rheumatic disease with ILD, what is the impact of abatacept compared to azathioprine as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

84. In people with rheumatic disease with ILD, what is the impact of JAK inhibitors compared to azathioprine as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

85. In people with rheumatic disease with ILD, what is the impact of nintedinib compared to azathioprine as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

86. In people with rheumatic disease with ILD, what is the impact of pirfenidone compared to azathioprine as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

87. In people with rheumatic disease with ILD, what is the impact of IVIG compared to azathioprine as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

88. In people with rheumatic disease with ILD, what is the impact of oral prednisone compared to azathioprine as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

89. In people with rheumatic disease with ILD, what is the impact of intravenous methylprednisolone compared to azathioprine as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

90. In people with rheumatic disease with ILD, what is the impact of plasma exchange compared to azathioprine as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

91. In people with rheumatic disease with ILD, what is the impact of methotrexate compared to cyclophosphamide as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

92. In people with rheumatic disease with ILD, what is the impact of leflunomide compared to cyclophosphamide as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

93. In people with rheumatic disease with ILD, what is the impact of calcineurin inhibitors compared to cyclophosphamide as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

94. In people with rheumatic disease with ILD, what is the impact of TNF inhibitors compared to cyclophosphamide as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

95. In people with rheumatic disease with ILD, what is the impact of IL-6 receptor antagonists (tocilizumab, sarilumab) compared to cyclophosphamide as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

96. In people with rheumatic disease with ILD, what is the impact of abatacept compared to cyclophosphamide as first line ILD treatment on disease-related outcomes and treatment-related

adverse events?

97. In people with rheumatic disease with ILD, what is the impact of JAK inhibitors compared to cyclophosphamide as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

98. In people with rheumatic disease with ILD, what is the impact of nintedinib compared to cyclophosphamide as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

99. In people with rheumatic disease with ILD, what is the impact of pirfenidone compared to cyclophosphamide as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

100. In people with rheumatic disease with ILD, what is the impact of IVIG compared to cyclophosphamide as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

101. In people with rheumatic disease with ILD, what is the impact of oral prednisone compared to cyclophosphamide as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

102. In people with rheumatic disease with ILD, what is the impact of intravenous methylprednisolone compared to cyclophosphamide as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

103. In people with rheumatic disease with ILD, what is the impact of plasma exchange compared to cyclophosphamide as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

104. In people with rheumatic disease with ILD, what is the impact of nintedanib compared to IL-6 receptor antagonists (tocilizumab, sarilumab) as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

105. In people with rheumatic disease with ILD, what is the impact of referral for stem cell transplant compared to optimal medical management as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

106. In people with rheumatic disease with ILD, what is the impact of referral for lung transplant compared to optimal medical management as first line ILD treatment on disease-related outcomes and treatment-related adverse events?

Rheumatic disease with ILD progression after any 1st ILD therapy

107. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding the combination of nintedanib and mycophenolate compared to adding mycophenolate alone on disease-related outcomes and treatment-related adverse events?

108. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding the combination of pirfenidone and mycophenolate compared to adding mycophenolate alone on disease-related outcomes and treatment-related adverse events?

109. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding methotrexate compared to adding mycophenolate on disease-related outcomes and treatment-related adverse events?

110. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding leflunomide compared to adding mycophenolate on disease-related outcomes and treatment-related adverse events?

111. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding azathioprine compared to adding mycophenolate on disease-related outcomes and treatment-related adverse events?

112. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding cyclophosphamide compared to adding mycophenolate on disease-related outcomes and treatment-related adverse events?

113. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding calcineurin inhibitors compared to adding mycophenolate on disease-related outcomes and treatment-related adverse events?

114. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding TNF inhibitors compared to adding mycophenolate on disease-related outcomes and treatment-

related adverse events?

115. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding IL-6 receptor antagonists (tocilizumab, sarilumab) compared to adding mycophenolate on disease-related outcomes and treatment-related adverse events?

116. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) compared to adding mycophenolate on disease-related outcomes and treatment-related adverse events?

117. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding abatacept compared to adding mycophenolate on disease-related outcomes and treatment-related adverse events?

118. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding JAK inhibitors compared to adding mycophenolate on disease-related outcomes and treatment-related adverse events?

119. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding nintedinib compared to adding mycophenolate on disease-related outcomes and treatment-related adverse events?

120. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding pirfenidone compared to adding mycophenolate on disease-related outcomes and treatment-related adverse events?

121. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding IVIG compared to adding mycophenolate on disease-related outcomes and treatment-related adverse events?

122. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding oral prednisone compared to adding mycophenolate on disease-related outcomes and treatment-related adverse events?

123. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding intravenous methylprednisolone compared to adding mycophenolate on disease-related

outcomes and treatment-related adverse events?

124. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding plasma exchange compared to adding mycophenolate on disease-related outcomes and treatment-related adverse events?

125. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding methotrexate compared to adding anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) on disease-related outcomes and treatment-related adverse events?

126. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding leflunomide compared to adding anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) on disease-related outcomes and treatment-related adverse events?

127. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding azathioprine compared to adding anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) on disease-related outcomes and treatment-related adverse events?

128. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding cyclophosphamide compared to adding anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) on disease-related outcomes and treatment-related adverse events?

129. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding calcineurin inhibitors compared to adding anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) on disease-related outcomes and treatment-related adverse events?

130. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding TNF inhibitors compared to adding anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) on disease-related outcomes and treatment-related adverse events?

131. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding IL-6 receptor antagonists (tocilizumab, sarilumab) compared to adding anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) on disease-related outcomes and treatment-related adverse events?

132. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding abatacept compared to adding anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab,

ofatumumab) on disease-related outcomes and treatment-related adverse events?

133. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding JAK inhibitors compared to adding anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) on disease-related outcomes and treatment-related adverse events?

134. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding nintedinib compared to adding anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) on disease-related outcomes and treatment-related adverse events?

135. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding pirfenidone compared to adding anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) on disease-related outcomes and treatment-related adverse events?

136. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding IVIG compared to adding anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) on disease-related outcomes and treatment-related adverse events?

137. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding oral prednisone compared to adding anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) on disease-related outcomes and treatment-related adverse events?

138. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding intravenous methylprednisolone compared to adding anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) on disease-related outcomes and treatment-related adverse events?

139. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding plasma exchange compared to adding anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) on disease-related outcomes and treatment-related adverse events?

140. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding methotrexate compared to adding azathioprine on disease-related outcomes and treatment-related adverse events?

141. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding leflunomide compared to adding azathioprine on disease-related outcomes and treatment-

related adverse events?

142. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding cyclophosphamide compared to adding azathioprine on disease-related outcomes and treatment-related adverse events?

143. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding calcineurin inhibitors compared to adding azathioprine on disease-related outcomes and treatment-related adverse events?

144. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding TNF inhibitors compared to adding azathioprine on disease-related outcomes and treatment-related adverse events?

145. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding IL-6 receptor antagonists (tocilizumab, sarilumab) compared to adding azathioprine on disease-related outcomes and treatment-related adverse events?

146. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding abatacept compared to adding azathioprine on disease-related outcomes and treatment-related adverse events?

147. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding JAK inhibitors compared to adding azathioprine on disease-related outcomes and treatment-related adverse events?

148. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding nintedinib compared to adding azathioprine on disease-related outcomes and treatment-related adverse events?

149. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding pirfenidone compared to adding azathioprine on disease-related outcomes and treatment-related adverse events?

150. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding IVIG compared to adding azathioprine on disease-related outcomes and treatment-related

adverse events?

151. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding oral prednisone compared to adding azathioprine on disease-related outcomes and treatment-related adverse events?

152. In people with rheumatic disease ILD progression after 1st ILD therapy, what is the impact of adding intravenous methylprednisolone compared to adding azathioprine on disease-related outcomes and treatment-related adverse events?

153. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding plasma exchange compared to adding azathioprine on disease-related outcomes and treatment-related adverse events?

154. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding methotrexate compared to adding cyclophosphamide on disease-related outcomes and treatment-related adverse events?

155. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding leflunomide compared to adding cyclophosphamide on disease-related outcomes and treatment-related adverse events?

156. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding calcineurin inhibitors compared to adding cyclophosphamide on disease-related outcomes and treatment-related adverse events?

157. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding TNF inhibitors compared to adding cyclophosphamide on disease-related outcomes and treatment-related adverse events?

158. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding IL-6 receptor antagonists (tocilizumab, sarilumab) compared to adding cyclophosphamide on disease-related outcomes and treatment-related adverse events?

159. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding abatacept compared to adding cyclophosphamide on disease-related outcomes and treatment-

related adverse events?

160. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding JAK inhibitors compared to adding cyclophosphamide on disease-related outcomes and treatment-related adverse events?

161. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding nintedinib compared to adding cyclophosphamide on disease-related outcomes and treatment-related adverse events?

162. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding pirfenidone compared to adding cyclophosphamide on disease-related outcomes and treatment-related adverse events?

163. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding IVIG compared to adding cyclophosphamide on disease-related outcomes and treatment-related adverse events?

164. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding oral prednisone compared to adding cyclophosphamide on disease-related outcomes and treatment-related adverse events?

165. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding intravenous methylprednisolone compared to adding cyclophosphamide on disease-related outcomes and treatment-related adverse events?

166. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of adding plasma exchange compared to adding cyclophosphamide on disease-related outcomes and treatment-related adverse events?

167. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of referral for stem cell transplant compared to optimal medical management on disease-related outcomes and treatment-related adverse events?

168. In people with rheumatic disease with ILD progression after 1st ILD therapy, what is the impact of referral for lung transplant compared to optimal medical management on disease-related outcomes and treatment-related adverse events?

Rheumatic disease with rapidly progressive ILD

169. In people with rheumatic disease with rapidly progressive ILD, what is the impact of daily oral prednisone compared to no daily oral prednisone as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

170. In people with rheumatic disease with rapidly progressive ILD, what is the impact of pulse intravenous glucocorticoids compared to no pulse intravenous glucocorticoids as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

171. In people with rheumatic disease with rapidly progressive ILD, what is the impact of nintedanib compared to no nintedanib as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

172. In people with rheumatic disease with rapidly progressive ILD, what is the impact of pirfenidone compared to no pirfenidone as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

173. In people with rheumatic disease with rapidly progressive ILD, what is the impact of adding nintedanib to mycophenolate compared to not adding nintedanib to mycophenolate as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

174. In people with rheumatic disease with rapidly progressive ILD, what is the impact of adding pirfenidone to mycophenolate compared to not adding pirfenidone to mycophenolate as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

175. In people with rheumatic disease with rapidly progressive ILD, what is the impact of upfront combination of nintedanib with mycophenolate compared to mycophenolate alone as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

176. In people with rheumatic disease with rapidly progressive ILD, what is the impact of upfront combination of pirfenidone with mycophenolate compared to mycophenolate alone as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

177. In people with rheumatic disease with rapidly progressive ILD, what is the impact of methotrexate compared to mycophenolate as first line rapidly progressive ILD treatment on disease-related outcomes

and treatment-related adverse events?

178. In people with rheumatic disease with rapidly progressive ILD, what is the impact of leflunomide compared to mycophenolate as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

179. In people with rheumatic disease with rapidly progressive ILD, what is the impact of azathioprine compared to mycophenolate as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

180. In people with rheumatic disease with rapidly progressive ILD, what is the impact of cyclophosphamide compared to mycophenolate as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

181. In people with rheumatic disease with rapidly progressive ILD, what is the impact of calcineurin inhibitors compared to mycophenolate as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

182. In people with rheumatic disease with rapidly progressive ILD, what is the impact of TNF inhibitors compared to mycophenolate as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

183. In people with rheumatic disease with rapidly progressive ILD, what is the impact of IL-6 receptor antagonists (tocilizumab, sarilumab) compared to mycophenolate as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

184. In people with rheumatic disease with rapidly progressive ILD, what is the impact of anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) compared to mycophenolate as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

185. In people with rheumatic disease with rapidly progressive ILD, what is the impact of abatacept compared to mycophenolate as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

186. In people with rheumatic disease with rapidly progressive ILD, what is the impact of JAK inhibitors compared to mycophenolate as first line rapidly progressive ILD treatment on disease-related outcomes

and treatment-related adverse events?

187. In people with rheumatic disease with rapidly progressive ILD, what is the impact of nintedinib compared to mycophenolate as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

188. In people with rheumatic disease with rapidly progressive ILD, what is the impact of pirfenidone compared to mycophenolate as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

189. In people with rheumatic disease with rapidly progressive ILD, what is the impact of IVIG compared to mycophenolate as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

190. In people with rheumatic disease with rapidly progressive ILD, what is the impact of oral prednisone compared to mycophenolate as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

191. In people with rheumatic disease with rapidly progressive ILD, what is the impact of intravenous methylprednisolone compared to mycophenolate as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

192. In people with rheumatic disease with rapidly progressive ILD, what is the impact of plasma exchange compared to mycophenolate as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

193. In people with rheumatic disease with rapidly progressive ILD, what is the impact of methotrexate compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

194. In people with rheumatic disease with rapidly progressive ILD, what is the impact of leflunomide compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

195. In people with rheumatic disease with rapidly progressive ILD, what is the impact of azathioprine compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line

rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

196. In people with rheumatic disease with rapidly progressive ILD, what is the impact of cyclophosphamide compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

197. In people with rheumatic disease with rapidly progressive ILD, what is the impact of calcineurin inhibitors compared to anti-CD20 (rituximab, ocrelizumab, obinutuzumab, ofatumumab) antibody as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

198. In people with rheumatic disease with rapidly progressive ILD, what is the impact of TNF inhibitors compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

199. In people with rheumatic disease with rapidly progressive ILD, what is the impact of IL-6 receptor antagonists (tocilizumab, sarilumab) compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

200. In people with rheumatic disease with rapidly progressive ILD, what is the impact of abatacept compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

201. In people with rheumatic disease with rapidly progressive ILD, what is the impact of JAK inhibitors compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

202. In people with rheumatic disease with rapidly progressive ILD, what is the impact of nintedinib compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

203. In people with rheumatic disease with rapidly progressive ILD, what is the impact of pirfenidone compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

204. In people with rheumatic disease with rapidly progressive ILD, what is the impact of IVIG compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

205. In people with rheumatic disease with rapidly progressive ILD, what is the impact of oral prednisone compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

206. In people with rheumatic disease with rapidly progressive ILD, what is the impact of intravenous methylprednisolone compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

207. In people with rheumatic disease with rapidly progressive ILD, what is the impact of plasma exchange compared to anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab) as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

208. In people with rheumatic disease with rapidly progressive ILD, what is the impact of methotrexate compared to azathioprine as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

209. In people with rheumatic disease with rapidly progressive ILD, what is the impact of leflunomide compared to azathioprine as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

210. In people with rheumatic disease with rapidly progressive ILD, what is the impact of cyclophosphamide compared to azathioprine as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

211. In people with rheumatic disease with rapidly progressive ILD, what is the impact of calcineurin inhibitors compared to azathioprine as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

212. In people with rheumatic disease with rapidly progressive ILD, what is the impact of TNF inhibitors compared to azathioprine as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

213. In people with rheumatic disease with rapidly progressive ILD, what is the impact of IL-6 receptor antagonists (tocilizumab, sarilumab) compared to azathioprine as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

214. In people with rheumatic disease with rapidly progressive ILD, what is the impact of abatacept compared to azathioprine as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

215. In people with rheumatic disease with rapidly progressive ILD, what is the impact of JAK inhibitors compared to azathioprine as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

216. In people with rheumatic disease with rapidly progressive ILD, what is the impact of nintedinib compared to azathioprine as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

217. In people with rheumatic disease with rapidly progressive ILD, what is the impact of pirfenidone compared to azathioprine as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

218. In people with rheumatic disease with rapidly progressive ILD, what is the impact of IVIG compared to azathioprine as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

219. In people with rheumatic disease with rapidly progressive ILD, what is the impact of oral prednisone compared to azathioprine as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

220. In people with rheumatic disease with rapidly progressive ILD, what is the impact of intravenous methylprednisolone compared to azathioprine as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

221. In people with rheumatic disease with rapidly progressive ILD, what is the impact of plasma exchange compared to azathioprine as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

222. In people with rheumatic disease with rapidly progressive ILD, what is the impact of methotrexate compared to cyclophosphamide as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

223. In people with rheumatic disease with rapidly progressive ILD, what is the impact of leflunomide compared to cyclophosphamide as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

224. In people with rheumatic disease with rapidly progressive ILD, what is the impact of calcineurin inhibitors compared to cyclophosphamide as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

225. In people with rheumatic disease with rapidly progressive ILD, what is the impact of TNF inhibitors compared to cyclophosphamide as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

226. In people with rheumatic disease with rapidly progressive ILD, what is the impact of IL-6 receptor antagonists (tocilizumab, sarilumab) compared to cyclophosphamide as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

227. In people with rheumatic disease with rapidly progressive ILD, what is the impact of abatacept compared to cyclophosphamide as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

228. In people with rheumatic disease with rapidly progressive ILD, what is the impact of JAK inhibitors compared to cyclophosphamide as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

229. In people with rheumatic disease with rapidly progressive ILD, what is the impact of nintedinib compared to cyclophosphamide as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

230. In people with rheumatic disease with rapidly progressive ILD, what is the impact of pirfenidone compared to cyclophosphamide as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

231. In people with rheumatic disease with rapidly progressive ILD, what is the impact of IVIG compared to cyclophosphamide as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

232. In people with rheumatic disease with rapidly progressive ILD, what is the impact of oral prednisone compared to cyclophosphamide as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

233. In people with rheumatic disease with rapidly progressive ILD, what is the impact of intravenous methylprednisolone compared to cyclophosphamide as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

234. In people with rheumatic disease with rapidly progressive ILD, what is the impact of plasma exchange compared to cyclophosphamide as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

235. In people with rheumatic disease with rapidly progressive ILD, what is the impact of dual combination therapy* compared to monotherapy† as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

236. In people with rheumatic disease with rapidly progressive ILD, what is the impact of triple combination therapy‡ compared to monotherapy† as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

237. In people with rheumatic disease with rapidly progressive ILD, what is the impact of triple combination therapy‡ compared to dual combination therapy* as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

238. In people with rheumatic disease with rapidly progressive ILD, what is the impact of using IVIG and/or plasma exchange in addition to monotherapy†, dual combination therapy*, or triple combination therapy‡ compared to using monotherapy†, dual combination therapy*, or triple combination therapy‡ alone as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

239. In people with rheumatic disease with rapidly progressive ILD, what is the impact of using an antifibrotic (e.g., nintedanib or pirfenidone) in addition to monotherapy†, dual combination therapy*, or triple combination therapy‡ compared to using monotherapy†, dual combination therapy*, or triple

combination therapy‡ alone as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

240. In people with rheumatic disease with rapidly progressive ILD, what is the impact of referral for stem cell transplant compared to optimal medical management as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

241. In people with rheumatic disease with rapidly progressive ILD, what is the impact of referral for lung transplant compared to optimal medical management as first line rapidly progressive ILD treatment on disease-related outcomes and treatment-related adverse events?

† Monotherapy examples: oral prednisone/intravenous methylprednisolone, or mycophenolate, or azathioprine, or a calcineurin inhibitor, or rituximab, or cyclophosphamide

* Dual combination therapy examples: oral prednisone/intravenous methylprednisolone and mycophenolate, or oral prednisone/intravenous methylprednisolone and azathioprine, or oral prednisone/intravenous methylprednisolone and a calcineurin inhibitor, or oral prednisone/intravenous methylprednisolone and rituximab, or oral prednisone/intravenous methylprednisolone and cyclophosphamide, or oral prednisone/intravenous methylprednisolone and a JAK inhibitor

‡ Triple combination therapy examples: oral prednisone/intravenous methylprednisolone and rituximab and cyclophosphamide, or oral prednisone/intravenous methylprednisolone and cyclophosphamide and a calcineurin inhibitor, or oral prednisone/intravenous methylprednisolone and mycophenolate and a calcineurin inhibitor, or oral prednisone/intravenous methylprednisolone and mycophenolate and abatacept, or oral prednisone/intravenous methylprednisolone and rituximab and mycophenolate

APPENDIX B – INCLUSION/EXCLUSION CRITERIA

POPULATIONS

Include

- Adults
- Rheumatoid arthritis, Systemic sclerosis (Scleroderma), Mixed Connective Tissue Disease (MCTD), Polymyositis, Dermatomyositis, MDA5 Dermatomyositis, Immune Mediated Necrotizing Myositis, Antisynthetase syndrome, Sjogren's syndrome
- Progressive Fibrosing ILD

Exclude

- Pediatrics (age 16 or younger)
- Juvenile scleroderma, juvenile systemic sclerosis, juvenile dermatomyositis, juvenile idiopathic arthritis
- Sarcoidosis, Interstitial Pneumonia with Autoimmune Features (IPAF), ankylosing spondylitis, ANCA-associated vasculitis, Systemic lupus erythematosus, Undifferentiated connective tissue disease
- Idiopathic Pulmonary Fibrosis
- Idiopathic interstitial pneumonias
- Unclassifiable ILD
- Overlap syndromes (e.g., SSc+myositis, RA+SSc, et)

INTERVENTIONS

Include

- Pulmonary Function Tests (PFTs)
- History/physical alone (e.g., shortness of breath (dyspnea), functional class and physician examination: crackles on auscultation)
- High resolution CT Thorax
- 6-minute walk test distance
- Ambulatory desaturation
- Chest radiograph (chest x-ray)
- Bronchoscopy (may include broncho-alveolar lavage, transbronchial biopsy)
- Surgical lung biopsy
- csDMARDs: methotrexate, leflunomide, azathioprine, cyclophosphamide, mycophenolate, calcineurin inhibitors (tacrolimus, cyclosporine)
- bDMARDs: TNF inhibitors (etanercept, adalimumab, infliximab, golimumab, certolizumab pegol), IL-6 receptor antagonists (tocilizumab, sarilumab), anti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab), abatacept

- tsDMARDs: JAK inhibitors (tofacitinib, baricitinib, upadacitinib)
- Others: Oral prednisone, intravenous methylprednisolone, intravenous immunoglobulin (IVIG), plasma exchange (plasmapheresis)
- Antifibrotics: Pirfenidone, Nintedanib
- Stem cell transplant (autologous, mesenchymal stem cells, hematopoietic, myeloablative, non-myeloablative)
- Lung Transplant

Exclude

- Vaccines: influenza, COVID-19, MMR, pneumococcus vaccine (refer to 2022 ACR vaccine guideline, presently in journal review; summary is online)
- Education (self-management of oxygen, ILD disease) *(will mention in Introduction or Discussion section)*
- Physiotherapy (chest physiotherapy, airway clearance, incentive spirometry), Exercise (aerobic, resistance training, yoga, tai chi), Pulmonary Rehabilitation (cardio-pulmonary rehabilitation, resistance training, in a center versus home)
- Oxygen (oxygen desaturation at rest, oxygen desaturation <88% with exercise)
- Palliative care (cough, pain, air hunger, end stage, end of life planning, when to initiate, what to initiate)
- Smoking cessation
- Fundoplication
- GI medications: proton pump inhibitors, H2 blockers, promotility agents
- Ibritumomab (is anti-CD20, but it is radioimmunotherapy)
- Basiliximab

COMPARATORS

Include

- No test
- History/physical alone (e.g., shortness of breath (dyspnea), functional class and physician examination: crackles on auscultation)
- High resolution CT Thorax
- Bronchoscopy (may include broncho-alveolar lavage, transbronchial biopsy, cryobiopsy)
- 6-minute walk test distance
- Ambulatory desaturation
- PFTs
- Placebo, no treatment
- Mycophenolate
- antiAnti-CD20 antibody (rituximab, ocrelizumab, obinutuzumab, ofatumumab)
- Azathioprine
- Cyclophosphamide

- Stem cell transplant (autologous, mesenchymal stem cells, hematopoietic, myeloablative, non-myeloablative)
- Lung transplant

OUTCOMES *(see Appendix C)*

STUDY DESIGN (includes only studies published in English language)

For all PICO questions, we will include randomized or non-randomized controlled trials (this includes case-control studies). To capture adverse events, we will also consider open-label extension studies of RCTs or other longitudinal observational studies that focus on safety and tolerability. For PICO questions that focus on assessing the accuracy of screening tools, we will also include studies without an independent control group, specifically cohort and cross-sectional studies. We will also include existing systematic reviews and guidelines from other societies **only** to confirm that we have included all relevant reference.

Include

- RCTs, including:
  - Open-label extensions of RCTs with placebo involved
- Non-randomized controlled studies, including
  - Case-control studies
- Cohort studies
- Cross-sectional studies
- Longitudinal studies (focusing on safety and tolerability)
- Systematic reviews and Guidelines from other societies

[NOTE: If there has been a recently done, well-done systematic review on the exact PICO that ACR is asking, then that systematic review could be considered for use in the guideline; primary study data would still need to be pulled in the ACR's database, though.]

Exclude

- Abstracts
- Case reports
- Narrative reviews
- Prevalence studies
- Economic studies, e.g., cost-effectiveness studies
- Drug adherence studies
- Studies of risk factors
- Foreign language studies
- Studies with irrelevant population, interventions, or outcomes
- Animal studies

APPENDIX C: OUTCOMES

Screening

Critical outcomes:

- Diagnostic accuracy
- Disease-related outcomes[1]
- Diagnostic testing-related adverse events

Monitoring

Critical outcomes:

- Responsiveness/sensitivity to change of the test
- Disease-related outcomes[1]
- Treatment-related serious adverse events
- Testing-related adverse events

Medical management

- Disease-related outcomes[1]
- Treatment-related adverse events

[1]**Critical outcomes:** mortality, disability, health related quality of life, adverse events (serious adverse events, toxicity leading to discontinuation). **Surrogate outcomes:** disease activity/disease progression defined by forced vital capacity (FVC), diffusion capacity for carbon monoxide (DLCO), CT thorax: extent of disease, disease progression.

APPENDIX D: DISCLOSURES

Participant Disclosures - American College of Rheumatology (ACR) Guideline for the Screening, Monitoring, and Treatment of Interstitial Lung Disease in Patients with Systemic Autoimmune Rheumatic Disease

In order for the College to most effectively further its mission and to otherwise maintain its excellent reputation in the medical community and with the public, it is important that confidence in the College's integrity be maintained. The cornerstone of the ACR's Disclosure Policy is disclosure of actual and potential conflicts so that they can be evaluated by the College in order to avoid undue influence of potential conflicts. The purpose of the ACR's Disclosure Policy is identification of relationships which may pose actual or potential conflicts. These actual or potential conflicts can then be evaluated by the College so that adjustments can be made that will avoid any undue influence. This policy is based on the principle that, in many cases, full disclosure of the actual or potentially conflicting relationship will of itself suffice to protect the integrity of the College and its interests.

Participants	Role	Primary Employer	Interest Held By	Interest Type	Entity/Licensee	Additional Information	Value
Sindhu R. Johnson	Core Team – PI	Toronto Western Hospital	Self	Independent Contractor - Editorial Board	Best Practice and Clinical Rheumatology		
			Self	Independent Contractor - Associate Editor	Journal of Rheumatology		
			Spouse/Partner	Independent Contractor - Editorial Board Member	Anesthesiology		
			Spouse/Partner	Independent Contractor - Editorial Board Member	Canadian Journal of Anesthesia		
			Spouse/Partner	Independent Contractor - Consultant	Edwards Lifesciences		
			Spouse/Partner	Independent Contractor - Consultant	Surgical Safety Technologies		
			Spouse/Partner	Independent Contractor - Editorial Board Member	Circulation Journal		
Elana Bernstein	Core Team - Co-first author	Columbia University/New York-Presbyterian Hospital	Self	Grant / Contract	U.S. Department of Defense		$750,000.00
			Self	Employment	James J. Peters VA Medical Center		
			Self	Employment	Columbia University		
			Self	Grant / Contract	Scleroderma Research Foundation	Columbia receives fees from the Scleroderma Research Foundation based on the number of new patient study visits and follow-up patient	$52,000.00

						study visits conducted.	
			Self	Grant / Contract	National Institutes of Health		$801,500.00
			Self	Independent Contractor - IC Iloprost for SSc-associated Raynaud's	Eicos	Total direct costs: $16,358.19 per patient	
			Self	Independent Contractor - Data And Safety Monitoring	UCLA Health System		$20,000.00
			Self	Independent Contractor - A Phase 2, Open-label, Multicenter Study to Evaluate the Efficacy and Safety of Belumosudil in dcSSc	Kadmon Pharmaceuticals LLC	Total direct costs: $40,697 per patient	
			Self	Grant / Contract	Boehringer Ingelheim		$500,000.00
			Self	Independent Contractor - Consultant	Boehringer Ingelheim		$6,526.25
			Self	Grant / Contract	Pfizer		$150,000.00
			Self	Independent Contractor - Scientific Advisory Board	Boehringer Ingelheim	I did not accept any compensation for participating in this Scientific Advisory Board.	

Marcy B. Bolster	Core Team - Content expert	Massachusetts General Hospital	Self	Grant / Contract	Genentech	Clinical trial I helped with data collection but did not receive salary support from this trial. I am not privy to the contracted amount. I thought I should disclose my relationship since my name is listed as a co-investigator and co-author on the publication. Please let me know if additional information is needed.	$1.00
			Self	Grant / Contract	Cumberland Pharmaceuticals	I am a co-investigator for this clinical trial	$31,699.00
			Self	Independent Contractor - Consultant	Merck Sharp & Dohme Corporation		
			Self	Independent Contractor - Associate Editor	PracticeUpdate		$10,000.00
			Self	Independent Contractor - Member, ABIM Rheumatology Longitudinal Assessment Program (LAP)Approval Committee	American Board of Internal Medicine		
			Self	Independent Contractor - Co-investigator	Corbus		
			custodial account with child who is no longer a dependent	Stock	Johnson and Johnson		$5,000.00
			Self	Independent Contractor - Principal Investigatory	Rheumatology Research Foundation	Grant recipient for salary support	
			Self	Independent Contractor - Principal Investigatory	Rheumatology Research Foundation	Grant recipient for salary support	

Jonathan H. Chung	Core Team - Content expert	University of Chicago				Nothing to disclose	
Sonye Danoff	Core Team - Content expert	Johns Hopkins University School of Medicine	Self	Grant / Contract	Boehringer Ingelheim	Open label extension of INBUILD clinical trial	$15,000.00
			Self	Grant / Contract	Boehringer Ingelheim		$500,000.00
			Self	Independent Contractor - Consultant	CSL Behring	This is a 4- hour virtual multi-disciplinary advisory board on autoimmune myositis	$3,000.00
			Self	Grant / Contract	Bristol Myers Squibb Company	This is a clinical trial of an LPA inhibitor in Progressive-fibrosing ILD	$125,000.00
			Self	Independent Contractor - Consultant	Boehringer Ingelheim		$2,600.00
			Self	Independent Contractor - Data And Safety Monitoring	Galapagos		$1,000.00
			Self	Employment	Pulmonary Fibrosis Foundation		
			Self	Fiduciary Officer	American Thoracic Society		
Michael George	Core Team - Content expert	Penn Medicine	Self	Independent Contractor - Consultant	AbbVie		$4,085.00
			Self	Employment	Perelman School of Medicine, University of Pennsylvania		
			Self	Independent Contractor - Consultant	Global Healthy Living Foundation		
			Self	Grant / Contract	GlaxoSmithKline		$61,000.00
			Self	Independent Contractor - Consultant	Dysimmune Diseases Foundation		$2,600.00
			Self	Independent Contractor - Consultant	Global Healthy Living Foundation		$3,000.00
Dinesh Khanna	Core Team - Content expert	University of Michigan	Self	Independent Contractor - Consultant	Genentech Foundation		$4,000.00
			Self	Independent Contractor - Consultant	CSL Behring		$1,000.00
			Self	Independent Contractor - Consultant	AbbVie		$4,000.00
			Self	Independent Contractor - Consultant	Actelion Pharmaceuticals		$6,000.00
			Self	Independent Contractor - Consultant	Prometheus		$5,000.00

			Self	Independent Contractor - Consultant	Horizon Pharma plc		$20,000.00
			Self	Stock Option	Eicos Sciences	Chief Medical Officer	
			Self	Independent Contractor - Consultant	Boehringer Ingelheim		$80,000.00
Ilya Ivlev	Core Team - Literature Review Co-Leader	ECRI Institute	Self	Grant / Contract	U.S. Department of Defense	Role-co-lead	$0.00
			Self	Grant / Contract	Agency for Healthcare Research and Quality	Goal 1: The purpose of this Task Order is to conduct systematic evidence reviews that the Task Force will use to make new or update existing recommendations Goal 2: To synthesize available evidence to support primary care guidelines development.	$0.00
			Self	Independent Contractor - Affiliate Investigator	Kaiser Permanente		
			Self	Grant / Contract	National Institute on Aging		$60,000.00
			Self	Employment	ECRI		
			Self	Grant / Contract	National Cancer Institute	To synthesize available evidence to support primary care guidelines development. Role: Research Curator, evidence synthesis for actionability	$0.00
			Self	Employment	Kaiser Permanente		
			Self	Grant / Contract	Agency for Healthcare Research and Quality		$300,000.00

Clinical Practice Guidelines by the Infectious Diseases Society of America (IDSA), American Academy of Neurology (AAN), and American College of Rheumatology (ACR): 2020 Guidelines for the Prevention, Diagnosis, and Treatment of Lyme Disease

Paul M. Lantos,[1] Jeffrey Rumbaugh,[2] Linda K. Bockenstedt,[3] Yngve T. Falck-Ytter,[4] Maria E. Aguero-Rosenfeld,[5] Paul G. Auwaerter,[6] Kelly Baldwin,[7] Raveendhara R. Bannuru,[8] Kiran K. Belani,[9] William R. Bowie,[10] John A. Branda,[11] David B. Clifford,[12] Francis J. DiMario Jr.,[13] John J. Halperin,[14] Peter J. Krause,[15] Valery Lavergne,[16] Matthew H. Liang,[17] H. Cody Meissner,[8] Lise E. Nigrovic,[18] James (Jay) J. Nocton,[19] Mikala C. Osani,[8] Amy A. Pruitt,[20] Jane Rips,[21] Lynda E. Rosenfeld,[3] Margot L. Savoy,[22] Sunil K. Sood,[23] Allen C. Steere,[11] Franc Strle,[24] Robert Sundel,[18] Jean Tsao,[25] Elizaveta E. Vaysbrot,[8] Gary P. Wormser,[26] and Lawrence S. Zemel[13]

It is important to realize that guidelines cannot always account for individual variation among patients. They are assessments of current scientific and clinical information provided as an educational service; are not continually updated and may not reflect the most recent evidence (new evidence may emerge between the time information is developed and when it is published or read); should not be considered inclusive of all proper treatments methods of care, or as a statement of the standard of care; do not mandate any particular course of medical care; and are not intended to supplant physician judgment with respect to particular patients or special clinical situations. Whether and the extent to which to follow guidelines is voluntary, with the ultimate determination regarding their application to be made by the physician in the light of each patient's individual circumstances. Although IDSA, AAN, and ACR make every effort to present accurate, complete, and reliable information, these guidelines are presented "as is" without any warranty, either express or implied. IDSA, AAN, and ACR (and their officers, directors, members, employees, and agents) assume no responsibility for any loss, damage, or claim with respect to any liabilities, including direct, special, indirect, or consequential damages, incurred in connection with these guidelines or reliance on the information presented.

The guidelines represent the proprietary and copyrighted property of IDSA, AAN, and ACR. Copyright 2020 Infectious Diseases Society of America, American Academy of Neurology, and American College of Rheumatology. All rights reserved. No part of these guidelines may be reproduced, distributed, or transmitted in any form or by any means, including photocopying, recording, or other electronic or mechanical methods, without the prior written permission of IDSA, AAN, or ACR. Permission is granted to physicians and healthcare providers solely to copy and use the guidelines in their professional practices and clinical decision-making. No license or permission is granted to any person or entity, and prior written authorization by IDSA, AAN, or ACR is required, to sell, distribute, or modify the guidelines, or to make derivative works of or incorporate the guidelines into any product, including but not limited to clinical decision support software or any other software product. Except for the permission granted above, any person or entity desiring to use the guidelines in any way must contact IDSA, AAN, or ACR for approval in accordance with the terms and conditions of third party use, in particular any use of the guidelines in any software product.

This evidence-based clinical practice guideline for the prevention, diagnosis, and treatment of Lyme disease was developed by a multidisciplinary panel representing the Infectious Diseases Society of North American (IDSA), the American Academy of Neurology (AAN), and the American College of Rheumatology (ACR). The scope of this guideline includes prevention of Lyme disease,

This guideline was jointly developed by the Infectious Diseases Society of America, the American Academy of Neurology Institute, and the American College of Rheumatology. The article was peer reviewed by *Arthritis & Rheumatology* and simultaneously published by *Clinical Infectious Diseases*, *Neurology*, *Arthritis Care & Research*, and *Arthritis & Rheumatology*. Each editor of the 4 journals appointed 1 reviewer for peer review. The articles

and the diagnosis and treatment of Lyme disease presenting as erythema migrans, Lyme disease complicated by neurologic, cardiac, and rheumatologic manifestations, Eurasian manifestations of Lyme disease, and Lyme disease complicated by coinfection with other tick-borne pathogens. This guideline does not include comprehensive recommendations for babesiosis and tick-borne rickettsial infections, which are published in separate guidelines. The target audience for this guideline includes primary care physicians and specialists caring for this condition such as infectious diseases specialists, emergency physicians, internists, pediatricians, family physicians, neurologists, rheumatologists, cardiologists, and dermatologists in North America.

Summarized below are the 2020 recommendations for the prevention, diagnosis, and treatment of Lyme disease. The panel followed a systematic process used in the development of other Infectious Diseases Society of America (IDSA), American Academy of Neurology (AAN), and American College of Rheumatology (ACR) clinical practice guidelines, which included a standardized methodology for rating the certainty of the evidence and strength of recommendation using the GRADE approach (Grading of Recommendations Assessment, Development, and Evaluation) (see Figure 1). A detailed description of background, methods, evidence summary and rationale that support each recommendation, and knowledge gaps can be found online in the full text (http://onlinelibrary.wiley.com/doi/10.1002/art.41562/abstract).

I. Which measures should be used to prevent tick bites and tick-borne infections?

A. Personal protective measures

Recommendation:

1. Individuals at risk of exposure should implement personal protective measures to reduce the risk of tick exposure and infection with tick-borne pathogens *(good practice statement).*

B. Repellents to prevent tick bites

Recommendation:

1. For the prevention of tick bites, we recommend N, N-Diethyl-meta-toluamide (DEET), picaridin, ethyl-3-(N-n-butyl-N- acetyl) aminopropionate (IR3535), oil of lemon eucalyptus (OLE), p-methane-3,8-diol (PMD), 2-undecanone, or permethrin *(strong recommendation, moderate-quality evidence)*.

C. Removal of attached ticks

Recommendations:

1. We recommend promptly removing attached ticks by mechanical means using a clean fine-tipped tweezer (or a comparable device) inserted between the tick body and the skin *(good practice statement)*.
2. We recommend against burning an attached tick (with a match or other heat device) or applying noxious chemicals or petroleum products to coax its detachment *(good practice statement)*.

II. Which diagnostic tests should be used following a tick bite?

A. Diagnostic tick testing

Recommendations:

1. We recommend submitting the removed tick for species identification *(good practice statement)*.

---

are identical except for minor stylistic and spelling differences in keeping with each journal's style. The full guideline is available at http://onlinelibrary.wiley.com/doi/10.1002/art.41562/abstract.

Support for this guideline was provided by the Infectious Diseases Society of America, the American Academy of Neurology, and the American College of Rheumatology.

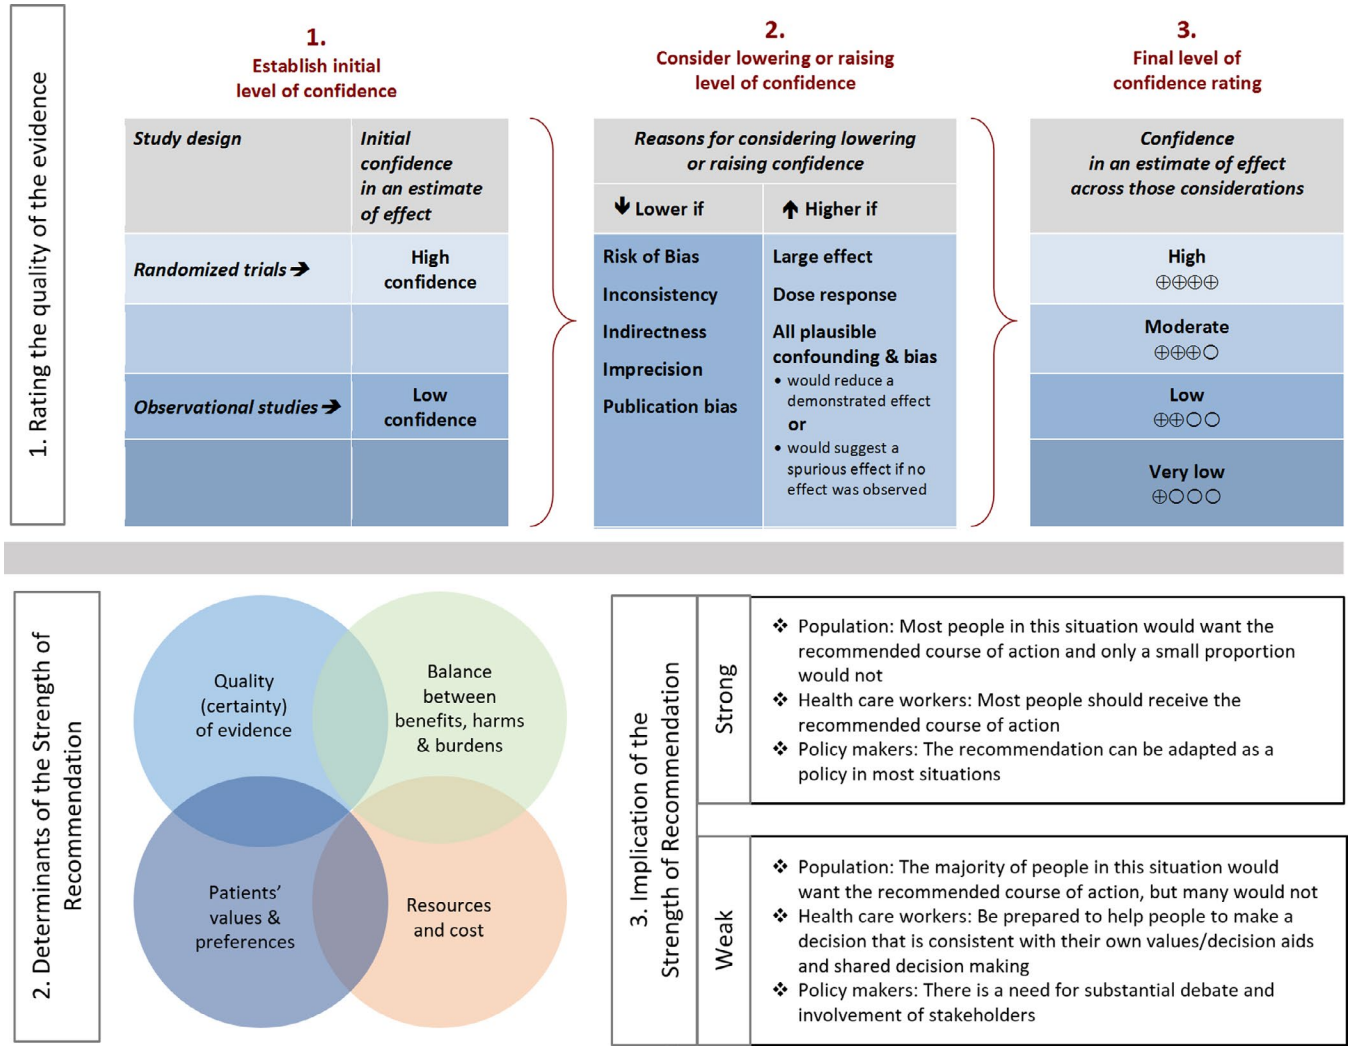
Submitted for publication August 21, 2019; accepted in revised form June 5, 2020.

[Correction added on 11 December, 2020 after first online publication: a paragraph was inserted on page 1, prior to the existing first paragraph.]



1. Rating the quality of the evidence
1.
Establish initial level of confidence
Study design
Initial confidence in an estimate of effect
Randomized trials
High confidence
Observational studies
Low confidence
2.
Consider lowering or raising level of confidence
Reasons for considering lowering or raising confidence
Lower if
Higher if
Risk of Bias
Inconsistency
Indirectness
Imprecision
Publication bias
Large effect
Dose response
All plausible confounding & bias
• would reduce a demonstrated effect
or
• would suggest a spurious effect if no effect was observed
3.
Final level of confidence rating
Confidence in an estimate of effect across those considerations
High
⊕⊕⊕⊕
Moderate
⊕⊕⊕○
Low
⊕⊕○○
Very low
⊕○○○
2. Determinants of the Strength of Recommendation
Quality (certainty) of evidence
Balance between benefits, harms & burdens
Patients' values & preferences
Resources and cost
3. Implication of the Strength of Recommendation
Strong
❖ Population: Most people in this situation would want the recommended course of action and only a small proportion would not
❖ Health care workers: Most people should receive the recommended course of action
❖ Policy makers: The recommendation can be adapted as a policy in most situations
Weak
❖ Population: The majority of people in this situation would want the recommended course of action, but many would not
❖ Health care workers: Be prepared to help people to make a decision that is consistent with their own values/decision aids and shared decision making
❖ Policy makers: There is a need for substantial debate and involvement of stakeholders

Figure 1. Approach and implications to rating the quality of evidence and strength of recommendations using the GRADE (Grading of Recommendations Assessment, Development, and Evaluation) methodology (unrestricted use of the figure granted by the US GRADE Network) (1,2).

2. We recommend against testing a removed *Ixodes* tick for *B. burgdorferi (strong recommendation, moderate-quality evidence)*. **Comment:** The presence or absence of *B. burgdorferi* in an *Ixodes* tick removed from a person does not reliably predict the likelihood of clinical infection.

B. Diagnostic testing of asymptomatic patients following tick bites

Recommendation:

1. We recommend against testing asymptomatic patients for exposure to *B. burgdorferi* following an *Ixodes* spp. tick bite *(strong recommendation, moderate-quality evidence).*

III. Who should receive antibiotic prophylaxis to prevent Lyme disease following presentation with a tick bite?

Recommendation:

1. We recommend that prophylactic antibiotic therapy be given only to adults and children within 72 hours of removal of an identified high-risk tick bite, but not for bites that are equivocal risk or low risk *(strong recommendation, high-quality evidence)*. **Comment**: If a tick bite cannot be classified with a high level of certainty as a high-risk bite, a wait-and-watch approach is recommended. A tick bite is considered to be high-risk only if it meets the following 3 criteria: the tick bite was from (a) an identified *Ixodes* spp. vector species, (b) it occurred in a highly endemic area, and (c) the tick was attached for ≥36 hours.

IV. What is the preferred antibiotic regimen for the chemoprophylaxis of Lyme disease following a high-risk tick bite?

Recommendation:

1. For high-risk *Ixodes* spp. bites in all age groups, we recommend the administration of a single dose of oral doxycycline within 72 hours of tick removal over observation *(strong recommendation, moderate-quality evidence)*. **Comment:** Doxycycline is given as a single oral dose, 200 mg for adults and 4.4 mg/kg (up to a maximum dose of 200 mg) for children.

V. What is the preferred diagnostic testing strategy for erythema migrans?

Recommendations:

1. In patients with potential tick exposure in a Lyme disease endemic area who have 1 or more skin lesions compatible with erythema migrans, we recommend clinical diagnosis rather than laboratory testing *(strong recommendation, moderate-quality evidence)*.
2. In patients with 1 or more skin lesions suggestive of, but atypical for erythema migrans, we suggest antibody testing performed on an acute-phase serum sample (followed by a convalescent-phase serum sample if the initial result is negative) rather than currently available direct detection methods such as polymerase chain reaction (PCR) or culture performed on blood or skin samples *(weak recommendation, low-quality evidence)*. **Comment:** If needed, the convalescent-phase serum sample should be collected at least 2–3 weeks after collection of the acute-phase serum sample.

VI. What are the preferred antibiotic regimens for the treatment of erythema migrans?

Recommendation:

1. For patients with erythema migrans, we recommend using oral antibiotic therapy with doxycycline, amoxicillin, or cefuroxime axetil *(strong recommendation; moderate-quality evidence)*. **Comment:** For patients unable to take both doxycycline and beta-lactam antibiotics, the preferred second-line agent is azithromycin.

VII. How long should a patient with erythema migrans be treated?

Recommendation:

1. We recommend that patients with erythema migrans be treated with either a 10-day course of doxycycline or a 14-day course of amoxicillin or cefuroxime axetil rather than longer treatment courses *(strong recommendation, moderate-quality evidence)*. **Comment:** If azithromycin is used, the indicated duration is 5–10 days, with a 7-day course preferred in the United States, as this duration of therapy was used in the largest clinical trial performed in the United States (3).

VIII. Should patients with the southern tick–associated rash illness (STARI) be treated with antibiotics?

Recommendation:

1. In patients who develop an erythema migrans–like skin lesion following the bite of the lone star tick (*Amblyomma americanum*), an illness referred to as STARI, we make no recommendation for or against the use of antibiotics *(no recommendation; knowledge gap)*. **Comment:** In certain geographic regions both STARI and Lyme disease are endemic (4). Distinguishing single erythema migrans due to Lyme disease from STARI may not be possible clinically unless the responsible tick has been identified (5). When STARI cannot be distinguished from Lyme disease–associated erythema migrans in areas endemic for both conditions, antibiotic therapy directed toward Lyme disease is indicated.

IX. What is the preferred diagnostic testing strategy for Lyme neuroborreliosis?

Recommendations:

1. When assessing patients for possible Lyme neuroborreliosis involving either the peripheral nervous system (PNS) or central nervous system (CNS), we recommend serum antibody testing rather than PCR or culture of either cerebrospinal fluid (CSF) or serum *(strong recommendation, moderate-quality evidence)*.

2. If CSF testing is performed in patients with suspected Lyme neuroborreliosis involving the CNS, we (a) recommend obtaining simultaneous samples of CSF and serum for determination of the CSF:serum antibody index, carried out by a laboratory using validated methodology, (b) recommend against CSF serology without measurement of the CSF:serum antibody index, and (c) recommend against routine PCR or culture of CSF or serum *(strong recommendation, moderate-quality evidence)*.

X. For which neurologic presentations should patients be tested for Lyme disease?

Recommendations:

1. In patients presenting with 1 or more of the following acute disorders: meningitis, painful radiculoneuritis, mononeuropathy multiplex including confluent mononeuropathy multiplex, acute cranial neuropathies (particularly VII, VIII, less commonly III, V, VI, and others), or in patients with evidence of spinal cord (or rarely brain) inflammation, the former particularly in association with painful radiculitis involving related spinal cord segments, and with epidemiologically plausible exposure to ticks infected with *B. burgdorferi*, we recommend testing for Lyme disease *(strong recommendation, moderate-quality evidence)*.
2. In patients with typical amyotrophic lateral sclerosis, relapsing-remitting multiple sclerosis, Parkinson's disease, dementia or cognitive decline, or new-onset seizures, we recommend against routine testing for Lyme disease *(strong recommendation, low-quality evidence)*.
3. In patients with neurologic syndromes other than those listed in [1] or [2], in the absence of a history of other clinical or epidemiologic support for the diagnosis of Lyme disease, we recommend against screening for Lyme disease *(strong recommendation, low-quality evidence)*.
4. In patients presenting with nonspecific magnetic resonance imaging white matter abnormalities confined to the brain in the absence of a history of other clinical or epidemiologic support for the diagnosis of Lyme disease, we suggest against testing for Lyme disease *(weak recommendation, low-quality evidence)*.

XI. Should adult patients with psychiatric illnesses be tested for Lyme disease?

Recommendation:

1. In patients with psychiatric illness, we recommend against routine testing for Lyme disease *(strong recommendation, low-quality evidence)*.

XII. Should children with developmental, behavioral, or psychiatric disorders be tested for Lyme disease?

Recommendation:

1. In children presenting with developmental, behavioral, or psychiatric disorders, we suggest against routinely testing for Lyme disease *(weak recommendation, low-quality evidence)*.

XIII. What are the preferred antibiotic regimens for the treatment of acute neurologic manifestations of Lyme disease without parenchymal involvement of the brain or spinal cord?

Recommendation:

1. In patients with Lyme disease–associated meningitis, cranial neuropathy, radiculoneuropathy, or with other PNS manifestations, we recommend using intravenous (IV) ceftriaxone, cefotaxime, penicillin G, or oral doxycycline over other antimicrobials *(strong recommendation, moderate-quality evidence)*. **Comment:** Decisions about the choice of antibiotic among these, including the route of administration, should primarily be made based on individual factors such as side effect profile, ease of administration, ability to tolerate oral medication, concerns about compliance unrelated to effectiveness. Treatment route may be changed from IV to oral during treatment. The preferred antibiotic duration is 14–21 days.

XIV. Should patients with Lyme disease–related parenchymal involvement of the brain or spinal cord be treated with oral or intravenous antibiotics?

Recommendation:

1. In patients with Lyme disease–associated parenchymal involvement of the brain or spinal cord, we recommend using IV over oral antibiotics *(strong recommendation, moderate-quality evidence)*.

XV. Should patients with Lyme disease and facial nerve palsy receive corticosteroids in addition to antimicrobial therapy?

Recommendation:

1. In patients with Lyme disease–associated facial nerve palsy, we make no recommendation on the use of corti-

costeroids in addition to antibiotics (no recommendation; knowledge gap). **Comment:** In patients age 16 or older presenting with acute facial nerve palsy but without other objective clinical or serologic evidence of Lyme disease, corticosteroid treatment should be administered within 72 hours in accordance with current facial nerve palsy guideline recommendations (6).

XVI. Should all patients with early Lyme disease receive an electrocardiogram (ECG) to screen for Lyme carditis?

Recommendation:

1. We suggest performing an ECG only in patients with signs or symptoms consistent with Lyme carditis *(weak recommendation, low-quality evidence)*. **Comment:** Symptoms and signs of cardiac involvement in Lyme disease include dyspnea, edema, palpitations, lightheadedness, chest pain, and syncope.

XVII. Which patients with Lyme carditis require hospitalization?

Recommendation:

1. In patients with or at risk for severe cardiac complications of Lyme disease including those with significant PR prolongation (PR >300 milliseconds), other arrhythmias, or clinical manifestations of myopericarditis, we recommend hospital admission with continuous ECG monitoring *(strong recommendation, very low-quality evidence).* **Comment:** Clinical manifestations of Lyme carditis include exercise intolerance, palpitations, presyncope, syncope, pericarditic pain, evidence of pericardial effusion, elevated biomarkers (such as troponin), edema, and shortness of breath.

XVIII. What pacing modality should be used if needed for the management of Lyme carditis?

Recommendation:

1. For patients with symptomatic bradycardia due to Lyme carditis that cannot be managed medically, we recommend temporary pacing modalities rather than implanting a permanent pacemaker *(strong recommendation, moderate-quality evidence)*.

XIX. What are the preferred antibiotic regimens for the treatment of Lyme carditis?

Recommendations:

1. In outpatients with Lyme carditis, we suggest oral antibiotics over IV antibiotics *(weak recommendation, very low-quality evidence)*.
2. In the hospitalized patient with Lyme carditis, we suggest initially using IV ceftriaxone over oral antibiotics until there is evidence of clinical improvement, then switching to oral antibiotics to complete treatment *(weak recommendation, very low-quality evidence)*.
3. For the treatment of Lyme carditis, we suggest 14–21 days of total antibiotic therapy over longer durations of treatment *(weak recommendation, very low-quality evidence)*. **Comment:** Oral antibiotic choices for Lyme carditis are doxycycline, amoxicillin, cefuroxime axetil, and azithromycin.

XX. Should patients being evaluated for acute myocarditis/pericarditis or chronic cardiomyopathy of unknown cause be tested for Lyme disease?

Recommendations:

1. In patients with acute myocarditis/pericarditis of unknown cause in an appropriate epidemiologic setting, we recommend testing for Lyme disease *(strong recommendation, low-quality evidence).*
2. In patients with chronic cardiomyopathy of unknown cause, we suggest against routine testing for Lyme disease *(weak recommendation, low-quality evidence)*.

XXI. What is the preferred diagnostic testing strategy for Lyme arthritis?

Recommendations:

1. When assessing possible Lyme arthritis, we recommend serum antibody testing over PCR or culture of blood or synovial fluid/ tissue *(strong recommendation, moderate-quality evidence)*.
2. In seropositive patients for whom the diagnosis of Lyme arthritis is being considered but treatment decisions require more definitive information, we recommend PCR applied to synovial fluid or tissue rather than *Borrelia* culture of those samples *(strong recommendation, moderate-quality evidence).*

XXII. What are the preferred antibiotic regimens for the initial treatment of Lyme arthritis?

Recommendation:

1. For patients with Lyme arthritis, we recommend using oral antibiotic therapy for 28 days *(strong recommendation, moderate-quality evidence)*.

XXIII. What are the approaches to patients in whom Lyme arthritis has not completely resolved?

Recommendations:

1. In patients with Lyme arthritis with partial response (mild residual joint swelling) after a first course of oral antibiotic, we make no recommendation for a second course of antibiotic versus observation *(no recommendation, knowledge gap)*. **Comment:** Consideration should be given to exclusion of other causes of joint swelling than Lyme arthritis, medication adherence, duration of arthritis prior to initial treatment, degree of synovial proliferation versus joint swelling, patient preferences, and cost. A second course of oral antibiotics for up to 1 month may be a reasonable alternative for patients in whom synovial proliferation is modest compared to joint swelling and for those who prefer repeating a course of oral antibiotics before considering IV therapy.
2. In patients with Lyme arthritis with no or minimal response (moderate to severe joint swelling with minimal reduction of the joint effusion) to an initial course of oral antibiotic, we suggest a 2–4-week course of IV ceftriaxone over a second course of oral antibiotics *(weak recommendation, low-quality evidence)*.

XXIV. How should post-antibiotic (previously termed antibiotic-refractory) Lyme arthritis be treated?

Recommendation:

1. In patients who have failed 1 course of oral antibiotics and 1 course of IV antibiotics, we suggest a referral to a rheumatologist or other trained specialist for consideration of the use of disease-modifying antirheumatic drugs, biologic agents, intraarticular steroids, or arthroscopic synovectomy *(weak recommendation, very low-quality evidence)*. **Comment:** Antibiotic therapy for longer than 8 weeks is not expected to provide additional benefit to patients with persistent arthritis if that treatment has included 1 course of IV therapy.

XXV. Should patients with persistent symptoms following standard treatment of Lyme disease receive additional antibiotics?

Recommendation:

1. For patients who have persistent or recurring nonspecific symptoms such as fatigue, pain, or cognitive impairment following recommended treatment for Lyme disease, but who lack objective evidence of reinfection or treatment failure, we recommend against additional antibiotic therapy *(strong recommendation, moderate-quality evidence)*. **Comment:** Evidence of persistent infection or treatment failure would include objective signs of disease activity, such as arthritis, meningitis, or neuropathy.

XXVI. What is the preferred antibiotic regimen for the treatment of borrelial lymphocytoma?

Recommendation:

1. In patients with borrelial lymphocytoma, we suggest oral antibiotic therapy for 14 days *(weak recommendation, low-quality evidence)*.

XXVII. What is the preferred antibiotic regimen for the treatment of acrodermatitis chronica atrophicans?

Recommendation:

1. In patients with acrodermatitis chronica atrophicans, we suggest oral antibiotic therapy for 21–28 days over shorter durations *(weak recommendation, low-quality evidence)*.

XXVIII. Under what circumstances should a patient with Lyme disease be evaluated for coinfection with *A. phagocytophilum* or *B. microti*?

Recommendation:

1. In patients with Lyme disease who have a high-grade fever or characteristic laboratory abnormalities, clinicians should assess for possible coinfection with *Anaplasma phagocytophilum* and/or *B. microti* infection in geographic regions where these infections are endemic *(good practice statement)*. **Comment:** Coinfection should be investigated in patients who have a persistent fever for >1 day while on antibiotic treatment for Lyme disease. If fever persists despite treatment with doxycycline, *B. microti* infection is an important consideration.

Characteristic laboratory abnormalities found in both anaplasmosis and babesiosis include thrombocytopenia, leukopenia, neutropenia, and/or anemia. Evidence of hemolysis, such as elevated indirect bilirubin level, anemia, and elevated lactate dehydrogenase, is particularly suggestive of babesiosis.

Supplementary data. Supplementary materials (in addition to the full guideline) are available on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41562/abstract. Consisting of data provided by the authors to benefit the reader, the posted materials are not copyedited and are the sole responsibility of the authors, so questions or comments should be addressed to the corresponding author.

Conflict of interest statement. See the Methodology section in the full guideline (on the *Arthritis & Rheumatology* website at http://onlinelibrary.wiley.com/doi/10.1002/art.41562/abstract) for approach to conflict of interest (COI) by the IDSA/AAN/ACR COI review group. The following list is a reflection of what has been reported to the IDSA/AAN/ACR COI review group. To provide thorough transparency, the IDSA/AAN/ACR requires full disclosure of all relationships, regardless of relevancy to the guideline topic. The assessment of disclosed relationships for possible COI is based on the relative weight of the financial relationship (i.e., monetary amount) and the relevance of the relationship (i.e., the degree to which an association might reasonably be interpreted by an independent observer as related to the topic or recommendation of consideration). The reader of these guidelines should be mindful of this when the list of disclosures is reviewed. Dr. Lantos has received research funding from the National Cytomegalovirus Foundation and from the NIH and educational funding from Duke University; and has served as a consultant and reviewed trial protocol for Frederick O'Connor Medical Consultants, LLC. Dr. Bockenstedt has received research funding from the NIH and the Gordon and Llura Gund Foundation; has received remuneration from L2 Diagnostics for investigator-initiated NIH-sponsored research; and was awarded an endowed professorship as the Harold W. Jockers Professor of Medicine at Yale University. Dr. Falck-Ytter serves as director of the Evidence Foundation and the GRADE Network; conducts GRADE workshops with the Evidence Foundation; has served as the chair of the Guidelines Committee for the American Gastroenterological Association; and has received research funding from the Cleveland VA Medical Research and Education Foundation. Dr. Agüero-Rosenfeld serves as a council member for the New York City chapter of the American Society of Microbiology (ASM) and as a Board member of the American Lyme Disease Foundation; has provided legal testimony and consultation regarding Lyme disease and tick-borne diseases; and has received research grants from the NIH, BioFire, New York State Department of Health, and ViraMed. Dr. Auwaerter receives research funding from the Fisher Center for Environmental Infectious Diseases and the NIH; serves on the Board of Directors of the American Lyme Disease Foundation and as the Vice Chair of the Infectious Diseases Society of America (IDSA) Foundation; serves as a scientific advisor for DiaSorin, Adaptive Technologies, and Shionogi; provides legal expert opinion testimony regarding Lyme disease; had stock in Johnson & Johnson; has served as an editor for Johns Hopkins POC-IT ABX Guide, an advisor for the Food and Drug Administration (FDA), Genentech, Dynavax, Aradigm, Cempra, BioMérieux, Cerexa, and Medscape; has received research funding from Cerexa; has served on the FDA Advisory Board, the Medscape Advisory Board, and the IDSA Board of Directors; and his spouse has equity interest in venture capital–funded Capricor. Dr. Belani reviews non-continuing medical education (CME) lectures for and received honoraria and travel reimbursement from Horizon Therapeutics; and has received research funding from the NIH and the Children's Hospitals and Clinics of Minnesota. Dr. Bowie has provided expert testimony to the Canadian Senate Subcommittee on Bill C-442: An Act Respecting a National Lyme Disease Strategy on behalf of the Association of Medical Microbiology and Infectious Disease Canada; and has received research funding from GlaxoSmithKline, Pfizer Canada, the Canadian Institutes of Health Research, and Vancouver Coastal Health Research Institute. Dr. Branda receives research funding from the Lyme Disease Biobank Foundation and Zeus Scientific; serves as a scientific advisor and consultant to DiaSorin, Inc.; has served as a scientific advisor and consultant for T2 Biosystems; has served on the scientific advisory board of Roche Diagnostics and AdvanDx; has received research funding from Karius, Inc., Alere, Inc., T2 Biosystems, BioMérieux, TBS Technologies, Immunetics, Inc., DiaSorin, Inc., Kephera Diagnostics, Inc., and the Bay Area Lyme Foundation; has participated in unfunded research collaborations with Karius Inc. and Kephera Diagnostics; was a member of the editorial board of the *Journal of Clinical Microbiology*; was a co-inventor on an application for a patent to protect intellectual property; and his spouse is an employee of Informed DNA. Dr. Clifford receives research funding from the NIH and the Alzheimer's Association; serves as scientific consultant to Inhibikase and Excision BioTherapeutics; serves on Data and Safety Monitoring Boards (DSMB) for Biogen, Genzyme/Sanofi, Genentech, EMD Serono, Shire, Wave Life Sciences, Pfizer, Atara, Mitsubishi Tanabe, and IQVIA (formerly Quintiles); serves on Progressive Multifocal Leukoencephalopathy (PML) adjudication committees for Amgen, GlaxoSmithKline, EMD Serono, Bristol Myers Squibb, Roche, and the Takeda Oncology (formerly Millennium) Adjudication Committee–FDA, as well as Dr. Reddy's Laboratories; has previously received research funding from the NIH; and his spouse formerly held stock in Johnson & Johnson. Dr. DiMario has received research funding from Novartis. Dr. Halperin serves as an Editorial Board Member of *Neurology*, and Vice Chair of the American Academy of Neurology (AAN) Guideline Subcommittee; has stock in Abbott Labs, AbbVie, Merck, and Johnson & Johnson; provides and has previously provided legal expert testimony defending physicians in medical malpractice cases on various neurologic issues, including Lyme disease; has received research funding from NIH, the Centers for Disease Control and Prevention (CDC); and has served as a section editor of neuroinfectious diseases in *Neurology & Neuroscience Reports*. Dr. Krause receives research funding from the Yale Emerging Infections Program; receives remuneration from Gold Standard Diagnostics for a collaborative research project; has stock in Gilead Sciences and First Trust NASDAQ Pharmaceuticals ETF; has received research funding from the NIH, the Centers for Disease Control and Prevention (CDC), the Gordon and Llura Gund Foundation, and L2 Diagnostics for NIH-sponsored research; has served as a scientific consultant and provided medical education and training for Oxford Immunotec, Inc.; has a patent pending (Enhanced Chemiluminescent enzyme-linked immunosorbent assay for detection of antibodies against *Babesia microti*), for which US Provisional Patent Application No. 62/580,588, was filed on November 2, 2017; serves on the Board of Directors for the American Lyme Disease Foundation and the Editorial Boards of Pathogens and *Plos* Neglected Tropical Diseases and the Editorial Advisory Board of *Clinical Infectious Diseases*; was on the Editorial Board of *Journal of Clinical Microbiology*, and will be on the Editorial Board of *Clinical Microbiology Reviews* starting January 2021. Dr. Liang has stock in Johnson & Johnson; received research funding from the Veterans Health Administration, the Arthritis Foundation, and the NIH; has served on the FDA Advisory Panel, Institute of Medicine panels; served as a scientific reviewer for the Research Grant Council of Hong Kong and the NIH; served on the Board of the Lupus Clinical Trials Consortium, Beacon Hill Villages, and Rx Foundation and advised the Institute for Clinical and Economic Review and the China Medical Board; previously had stock in Sequenom; and his spouse has stock in Johnson & Johnson. Dr. Meissner is a current member of the CDC Workgroups and serves as a volunteer consultant on the American Academy of Pediatrics Committee on Infectious Diseases and the NIH DSMB. Dr. Nigrovic receives research funding from the NIH, Department of Defense, and the NIH Center for Research Resources and for Advancing Translational Sciences (NCATS), Global Lyme Alliance, and Peabody Foundation; serves on the Editorial Board for *Annals of Emergency Medicine*; has served as scientific consultant for Adaptive Technologies; has received research funding from the NIH, Provider and Payer Quality Initiative (PPQI) Research Foundation, Harvard Catalyst, Hood Foundation, Bay Area Lyme Foundation, CDC, Emergency Medical Services for Children (EMSC), the National Patient-Centered Clinical Research Network (PCORNet), Milton Foundation, and Boston Children's Hospital. Dr. Nocton receives research funding from Bristol Myers Squibb; serves as

a member of the Subboard of Pediatric Rheumatology of the American Board of Pediatrics; and has received research funding from AbbVie, NIH, and the Arthritis Foundation. Dr. Pruitt has received research funding from Teva Pharmaceuticals and has served on the AAN Editorial Board of *Neurology Clinical Practice*. Ms Rips has received research funding from the Center for AIDS Research, Biogen Idec, Hoffmann-LaRoche, Sun Pharmaceutical Industries Ltd., Genzyme, the Alzheimer's Association, and the American College of Radiology; and has served as a speaker for Teva Pharmaceuticals. Dr. Rosenfeld serves as a Council Member of the American College of Cardiology; has stock in Abbott, Proctor & Gamble, and General Electric; has received Fellowship Support from Boston Scientific, Medtronic, and Abbott Laboratories (formerly St. Jude Medical); has received research funding from Boehringer Ingelheim Pharmaceuticals, Inc.; and has served on the Program Committee and the Patient and Caregivers Committee of the Heart Rhythm Society. Dr. Savoy serves on the American Academy of Family Physicians (AAFP) Board of Directors, as an ex-officio Board member of Delaware Academy of Family Physicians (DAFP), as the Chair of the Centers for Medicare and Medicaid Services (CMS) Advisory Panel on Outreach and Education, and as Secretary of the Board of Directors of the Association of Departments of Family Medicine; receives honoraria from AAFP, DAFP, CMS, and Merck; has served on an Advisory Council for Highmark Health and as an advisor to the AAFP Adolescent Immunization Project; has received honoraria from AAFP; has served as the President of DAFP, as Editor of *DelFamDoc*, and as a member of AAFP Commissions. Dr. Sood has received research funding from the NIH; and has provided expert testimony for Danaher Lagnese, PC. Dr. Steere receives research funding from the NIH and the Mathers Foundation; has received research funding from the NIH, the American College of Rheumatology, the Mathers Foundation, the English-Bonter-Mitchell Foundation, Immunetics, Inc., Zeus Diagnostics, and the Ounsworth-Fitzgerald Foundation; and has served as a scientific advisor for Baxter Bioscience Institute of Systems Biology, Immunetics, Inc., Roche Diagnostics, and Viramed. Dr. Strle receives research funding from the Slovenian Research Agency; serves as the Head of Health Counsel of the Ministry of Health of the Republic of Slovenia and as a member of the Steering Committee for the European Society of Clinical Microbiology and Infectious Diseases Study Group for Lyme Borreliosis; serves on the Roche Diagnostics Advisory Board on Lyme Disease Diagnostics; and has received honoraria from Roche Diagnostics. Dr. Sundel receives research funding from the NIH and AbbVie, Inc.; serves as a content author and editor for UpToDate; provides expert testimony to Chin-Caplan, PC; has provided expert testimony for Conway Homer, PC; has served as an advisor for Paul Hastings, LLC; has served as a content editor for SimulConsult and as a Medical Education Resources lecturer for CME-granting educational courses; has received remuneration from SimulConsult as a co-investigator for an NIH-sponsored grant; and has received research funding from the NIH. Dr. Tsao receives research funding from the National Science Foundation, NIH, CDC, the Michigan Lyme Disease Association, and the Michigan Department of Health and Human Services; serves as a Scientific Council Advisor Member for the Canadian Lyme Disease Research Network and as a scientific advisor for the American Lyme Disease Association; has received research funding from Michigan State University; has served as an Associate Editor for *Ticks and Tick-Borne Diseases* and on the Tick Vectors, Surveillance, and Prevention Subcommittee of the US Department of Health and Human Services Tick-Borne Disease Working Group; and has received remuneration for providing educational seminars for Boehringer Ingelheim (formerly Merial). Dr. Wormser receives research funding from Immunetics, Inc., Rarecyte, Inc., Institute for Systems Biology, and Quidel Corporation; serves on the Board of the American Lyme Disease Foundation; provides and has previously provided expert testimony in malpractice cases; has stock in AbbVie, Inc. and Abbott Laboratories; has received research funding from the CDC, NIH, BioMérieux, Bio-Rad Laboratories, and DiaSorin, Inc; has served as a scientific research advisor for Baxter International and as a Lyme disease advisor and expert for the Missouri Board of Registration for the Healing Arts; has a patent approved (US patent no. 10,669,567 B2) for High Sensitivity Method for Early Lyme Disease Detection; filed 2 patent applications related to early Lyme disease detection (application no: 62/277,252) and Lyme arthritis and post-treatment Lyme disease syndrome (application no: 62/725,745); and has served on the Editorial Boards for *Clinical Infectious Diseases*, *Vector-Borne and Zoonotic Diseases*, and *Ticks and Tick-Borne Diseases*. Dr. Zemel has served as an advisor for Novartis Promotional Speakers Bureau. No other disclosures relevant to this article were reported. All authors have submitted the ICMJE Form for Disclosure of Potential Conflicts of Interest. Conflicts that the editors consider relevant to the content of the manuscript have been disclosed.

ACKNOWLEDGMENTS

The expert panel expresses its gratitude for thoughtful reviews of an earlier version to the external reviewers. The panel thanks the IDSA, AAN, and ACR for supporting the guideline development process.

AUTHOR CONTRIBUTIONS

All authors were involved in drafting the article or revising it critically for important intellectual content, and all authors approved the final version to be published. Dr. Lantos had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Objective. **To develop criteria for the classification of macrophage activation syndrome (MAS) in patients with systemic juvenile idiopathic arthritis (JIA).**

Methods. **A multistep process, based on a combination of expert consensus and analysis of real patient data, was conducted. A panel of 28 experts was first asked to classify 428 patient profiles as having or not having MAS, based on clinical and laboratory features at the time of disease onset. The 428 profiles comprised 161 patients with systemic JIA–associated MAS and 267 patients with a condition that could potentially be confused with MAS (active systemic JIA without evidence of MAS, or systemic infection). Next, the ability of candidate criteria to classify individual patients as having MAS or not having MAS was assessed by evaluating the agreement between the classification yielded using the criteria and the consensus classification of the experts. The final criteria were selected in a consensus conference.**

Results. **Experts achieved consensus on the classification of 391 of the 428 patient profiles (91.4%). A total of 982 candidate criteria were tested statistically. The 37 best-performing criteria and 8 criteria obtained from the literature were evaluated at the consensus conference. During the conference, 82% consensus among experts was reached on the final MAS classification criteria. In validation analyses, these criteria had a sensitivity of 0.73 and a specificity of 0.99. Agreement between the classification (MAS or not MAS) obtained using the criteria and the original diagnosis made by the treating physician was high ($\kappa = 0.76$).**

Conclusion. **We have developed a set of classification criteria for MAS complicating systemic JIA and provided preliminary evidence of its validity. Use of these criteria will potentially improve understanding of MAS in systemic JIA and enhance efforts to discover effective therapies, by ensuring appropriate patient enrollment in studies.**

Introduction

Macrophage activation syndrome (MAS) is the term used to describe a potentially life-threatening complication of systemic inflammatory disorders, which occurs most commonly in systemic juvenile idiopathic arthritis (JIA) and in its adult equivalent, adult-onset Still's disease (1–4), although its occurrence in patients with other autoimmune or autoinflammatory conditions, i.e., adult- and childhood-onset systemic lupus erythematosus (5,6), Kawasaki disease (7,8), and periodic fever syndromes (9,10), is being reported with increased frequency. MAS is characterized by an overwhelming inflammatory reaction due to an uncontrolled and dysfunctional immune response involving the continual activation and expansion of T lymphocytes and macrophages, which results in massive hypersecretion of proinflammatory cytokines (11,12).

Characteristic clinical features of MAS are high, nonremitting fever, hepatosplenomegaly, generalized lymphadenopathy, central nervous system dysfunction, and hemorrhagic manifestations. Typical laboratory abnormalities include pancytopenia, increased levels of ferritin, liver enzymes, lactate dehydrogenase, triglycerides, D-dimers, and soluble interleukin-2 (IL-2) receptor α (also known as soluble CD25 [sCD25]), and decreased fibrinogen levels. A typical histopathologic feature of MAS is the accumulation of well-differentiated macrophages exhibiting hemophagocytic activity in bone marrow biopsy specimens or aspirates (13). Although the prevalence of MAS among patients with systemic JIA has been estimated to be ~10%, recent reports suggest that subclinical MAS may occur in as many as 30-40% of patients with systemic JIA (14,15).

MAS can result in progressive multi-organ failure and eventually a fatal outcome if unrecognized. Recent studies indicate a mortality rate of 8% (16,17), making

timely diagnosis and prompt initiation of appropriate treatment imperative. However, early recognition of MAS is often challenging, given the lack of a single pathognomonic clinical or laboratory feature. Furthermore, histopathologic features of hemophagocytosis may not be present in the initial stages (18,19) and lack specificity for hemophagocytic syndromes (20). In addition, features of MAS may be difficult to distinguish from other conditions that may present with overlapping manifestations, such as flares of systemic JIA or systemic infections. Recently, a wide disparity in the frequency and severity of the classic clinical and laboratory features across patients has been described (16,17).

The difficulties in making the diagnosis of MAS and its clinical heterogeneity, together with the recent advances in its treatment and in understanding of its pathophysiology and underlying genetic defects (11,21–23), emphasize the need for accurate criteria to aid physicians in appropriately classifying patients as having MAS to facilitate enrollment into clinical studies. The recognition that the syndrome is clinically similar to hemophagocytic lymphohistiocytosis (HLH) has led some to recommend the use of the HLH-2004 diagnostic guidelines (24). An alternative approach is based on application of the preliminary diagnostic guidelines for MAS complicating systemic JIA (25). However, although both sets of guidelines have been utilized for detecting MAS in patients with systemic JIA, each has several limitations (26). The primary purpose of the international collaborative project described herein, conducted under the auspices of the European League Against Rheumatism, the American College of Rheumatology, and the Paediatric Rheumatology International Trials Organisation (PRINTO), was to develop a set of classification criteria for MAS complicating systemic JIA, based on a combination of expert consensus, available evidence from the medical literature, and analysis of real patient data.

Methods

A multistep process was used in developing the classification criteria and included the following phases: 1) a Delphi survey of international pediatric rheumatologists, aimed at identifying MAS features potentially suitable for inclusion in classification criteria (27); 2) large-scale data collection on patients with systemic JIA–associated MAS and patients with 2 other conditions that potentially could be confused with MAS; 3) a web-based procedure for ascertaining consensus among experts; 4) selection of candidate criteria through statistical analyses; 5) selection of final classification criteria in a consensus conference; and 6) cross-sectional validation of final classification criteria. Health professionals and patient/parent representatives were not included in the study task force because the project did not involve any issues of specific interest to these stakeholders. In particular, none of the study assessments required the participation of health professionals, and no patient/parent-reported outcomes were incorporated.

Data collection on patients with MAS and patients with conditions that could be confused with MAS. The design, inclusion criteria, and data collection procedures of this portion of the project have been described in detail previously (16,17,26). Briefly, international pediatric rheumatologists and pediatric hematologists were invited to participate in a retrospective cohort study of patients with systemic JIA–associated MAS or with 1 of 2 conditions that could potentially be confused with MAS, i.e., active systemic JIA not complicated by MAS and systemic infection.

For patients with MAS, information on laboratory features at 3 time points (the last visit before onset of MAS, the time of MAS onset, and the period of full-blown MAS) was collected. Because the classification criteria were aimed at identification of MAS in its earlier stages, only laboratory data recorded at the time of onset were retained. Data at the time of presentation in patients with conditions that could be confused with MAS were also obtained. Except for blood cell counts and acute-phase reactant levels, values of laboratory parameters were tested using both the original values provided by each local laboratory and the values standardized according to the SI unit system based on their normal ranges, as previously reported (16).

A total of 1,111 patients (362 with systemic JIA–associated MAS, 404 with active systemic JIA without MAS, and 345 with systemic infection) were reported by 95 pediatric subspecialists practicing in 33 countries in 6 continents. Pediatric subspecialists who provided these data are listed in Appendix A. The features of the patients with MAS and the comparison patients have been described elsewhere (16,17,26).

Web-based procedures for ascertaining consensus among experts. At present, there is no single feature that is pathognomonic for MAS. Furthermore, no prior validated diagnostic or classification criteria are available. In order to classify patients as having or not having MAS, we therefore decided to use expert consensus as the "gold standard." Based on publication records and experience in the care of children with MAS and related disorders, a panel of 28 experts (20 pediatric rheumatologists and 8 pediatric hematologists) was created.

The experts were asked to classify a total of 428 patient profiles as having or not having MAS, based on the clinical and laboratory features recorded at disease onset. The 428 profiles were selected randomly from among the 1,111 patients whose data were collected and comprised 161 patients with MAS, 140 patients with active systemic JIA without evidence of MAS, and 127 patients with systemic infection. Selection bias was unlikely, as the characteristics of patients who were selected and those who were not selected were comparable (data not shown). The experts were intentionally kept unaware of the original diagnosis and overall course of each patient.

Each patient profile included information about the presence or absence of key clinical manifestations, and the values of laboratory parameters and normal ranges at the respective institutions. Based on these data, all experts were asked to classify each patient as having or not having MAS. The minimum required level of agreement among experts was set at 80%. If an 80% consensus was not attained, the patient profile was discussed in a further round. Profiles for which consensus had not been achieved after the final round were declared

uninterpretable and discarded from further analyses. Three rounds of voting were used, with prior vote data and recorded comments available to all of the participants before each vote took place, to augment the number of consensus decisions. All web-based consensus procedures were conducted by PRINTO.

Selection of best classification criteria through statistical analyses. All statistical analyses used for selecting the best classification criteria were conducted only on the sample of patients for whom the experts achieved consensus about the diagnosis of MAS or non-MAS. Cutoff values for laboratory tests were calculated with the receiver operator characteristic (ROC) curve method, by identifying the point on the ROC curve that best discriminated between patients classified by the experts as having MAS and those classified as not having MAS.

The aim of this exercise was to assess the ability of candidate criteria to classify individual patients as having or not having MAS, and to evaluate the agreement between the classification yielded by the criteria and the consensus classification of experts. Candidate classification criteria were partly derived from the literature and partly generated from the study data.

Literature criteria included the following: 1) the preliminary diagnostic guidelines for MAS complicating systemic JIA (25), 2) the same guidelines modified by addition of the item ferritin at various threshold levels (500, 1,000 or 1,500 ng/ml), and 3) the HLH-2004 diagnostic guidelines (24), adapted by eliminating 3 of the 8 items because information about presence of hemophagocytosis was not available for both comparison groups, and neither natural killer (NK) cell activity nor sCD25 levels were determined in all patients. Criteria obtained from the study data were generated in 2 ways: 1) through the evaluation, by the project steering committee, of all combinations of clinical and laboratory variables (see some examples in Supplementary Table 1, on the *Arthritis & Rheumatology* web site at http://onlinelibrary.wiley.com/doi/10.1002/art.39332/abstract) (combination of criteria approach), and 2) by assigning weights to clinical and laboratory variables, on the basis of their association with the diagnosis of MAS made by the experts, through multivariable logistic regression analysis. For each combination of variables that were significantly associated with the diagnosis of MAS in logistic regression models, the rule was to convert the odds ratio of each variable to its percentage value out of a total of 100%. Each set of criteria was then composed of a group of variables whose sum of weights made up a total score of 100 (MAS score). The cutoff value in the MAS score that was associated with the higher likelihood of the presence of MAS was obtained by calculating the point on the ROC curve that corresponded to the highest sensitivity and specificity.

A total of 982 candidate classification criteria were tested. For each set of criteria, we calculated the sensitivity (ability of the criteria to identify a patient as having MAS who had been classified as having MAS according to the expert panel), the specificity (ability of the criteria to identify a patient as not having MAS who had been classified as not having MAS by the experts), the positive and negative predictive value, the area under the ROC curve (AUC), and the kappa value for agreement between the classification yielded by the criteria and the classification made by the experts. Although

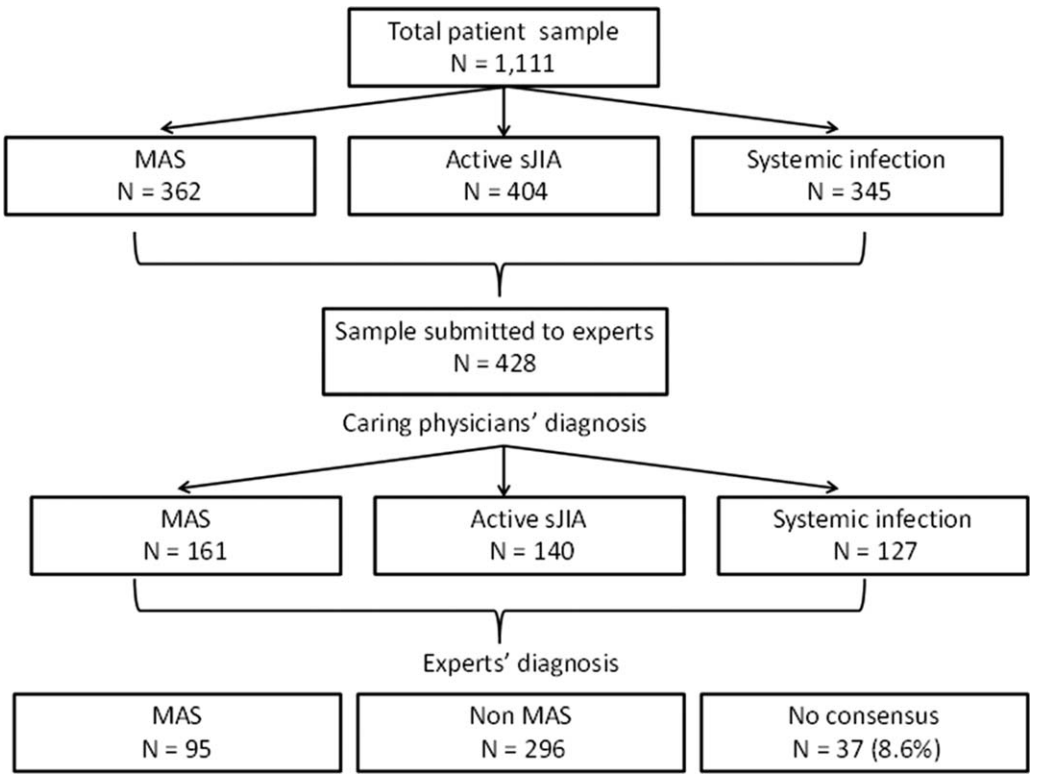

Figure 1. Patient samples evaluated in the study and results of web-based expert evaluations. MAS = macrophage activation syndrome; sJIA = systemic juvenile idiopathic arthritis.

there was one single model with the highest predictive value (criterion no. 929; Supplementary Table 1), we generated multiple combinations for comparison because we believed that less predictive models might have more face validity with the experts. Nevertheless, it was established that in order to qualify for inclusion in expert voting procedures at the consensus conference, a set of classification criteria should demonstrate a kappa value of ≥0.85, a sensitivity of ≥0.80, a specificity of ≥0.93, and an AUC of ≥0.90. An exception was made for the historical literature criteria, which were retained for further consideration even if they did not meet all statistical requirements.

Selection of the final classification criteria at consensus conference. The International Consensus Conference on MAS Classification Criteria was held in Genoa, Italy on March 21–22, 2014. The meeting was attended by all 28 experts who participated in web-based consensus evaluations and was facilitated by 2 moderators (HIB and NR) with expertise in nominal group technique. The overall goal of the meeting was to decide on a preliminary set of classification criteria using a combination of statistical and consensus formation techniques.

A plenary session was first held to present the scope, methodology, and flow of the project, the results of the Delphi survey, the characteristics of patients included in the data collection, the results of web-based consensus procedures and of statistical analyses of candidate classification criteria, and the methodology of the nominal group technique. Participants were then randomized into 2 equal-sized nominal groups and were asked to rank using nominal group technique, independently of each other and based on the evaluation of both ease of use and credibility (face/content validity) and statistical performance (particularly in terms of sensitivity, specificity, and kappa value), the 5 best classification criteria from 5 (highest) to 1 (lowest). All experts were connected by their laptops to a central computer and submitted all of their rankings electronically. A series of repeated independent voting sessions was held until the top 3 classification criteria were selected by each voting group. Then an 80% consensus was attained on the best (final) set of classification criteria, in a session with members of the 2 nominal groups combined.

Analysis of the association between the variables included in the final classification criteria and the web-based experts' consensus evaluations. The association between the final classification criteria and the web-based evaluations made by the experts was assessed by multiple logistic regression analysis, which used as explanatory variables the individual items included in the final classification criteria and as the dependent variable the web-based expert consensus on classification of patients as having or not having MAS. The effect was expressed in terms of odds ratios, and 95% confidence intervals were calculated; statistical significance was tested by likeli-

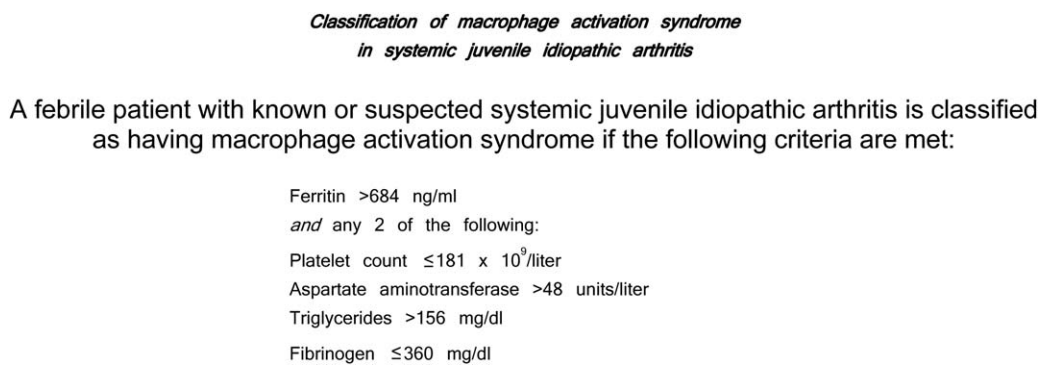
* OR = odds ratio; 95% CI = 95% confidence interval.

hood ratio test. The AUC of the model was used as an indicator of its predictive ability. The purpose of this post-consensus analysis was to evaluate which were the variables that most influenced the experts' decision to classify the patients as having or not having MAS.

Validation of final classification criteria. Validation analysis was performed by assessing the performance of the criteria, in terms of sensitivity, specificity, negative predictive value, positive predictive value, AUC, and kappa value, in discriminating patients with MAS from patients with the 2 conditions with which MAS could be confused (combined in a single group), using the original diagnosis made by the caring physician (i.e., the investigator who entered the patient's data in the study web site) as the gold standard. This analysis was performed on the sample of patients not used for expert evaluations (n = 683). Only patients with available data on all items included in the final classification criteria were used for the analyses.

Results

Results of web-based process for ascertainment of expert consensus. After 3 rounds of web-based evaluations, the experts achieved consensus on the classification of 391 (91.4%) of the 428 patient profiles examined (Figure 1). A total of 95 patients were classified as having MAS by the experts, 88 of whom had also been diagnosed as having MAS by the treating physician; the original diagnosis had been systemic JIA without MAS in 3 patients and systemic infection in 4. A total of 296 patients were classified by the experts as not having MAS, 47 of whom had been diagnosed as having MAS by the treating physician. Thirty-seven patient profiles for which 80% consensus among experts was not reached were discarded. A comparison of



Classification of macrophage activation syndrome
in systemic juvenile idiopathic arthritis
A febrile patient with known or suspected systemic juvenile idiopathic arthritis is classified as having macrophage activation syndrome if the following criteria are met:
Ferritin >684 ng/ml
and any 2 of the following:
Platelet count ≤181 x 10^9/liter
Aspartate aminotransferase >48 units/liter
Triglycerides >156 mg/dl
Fibrinogen ≤360 mg/dl

Figure 2. Criteria for the classification of macrophage activation syndrome in patients with systemic juvenile idiopathic arthritis. Laboratory abnormalities should not be otherwise explained by the patient's condition, such as concomitant immune-mediated thrombocytopenia, infectious hepatitis, visceral leishmaniasis, or familial hyperlipidemia.

clinical and laboratory features between patients diagnosed by the experts as having MAS and those diagnosed as not having MAS is shown in Table 1. Overall, patients whose condition was classified as MAS by the experts had more severe clinical and laboratory features than those classified as not having MAS.

Candidate clinical and laboratory variables determined by univariate analysis. In univariate analyses, the 10 variables found to have the greatest ability to distinguish patients with MAS from comparison patients were as follows: ferritin level, platelet count, levels of aspartate transaminase (AST), lactate dehydrogenase, triglycerides, alanine transaminase (ALT), and fibrinogen, central nervous system involvement, hepatomegaly, and hemorrhagic manifestations (Table 2). These variables qualified for inclusion in logistic regression analyses aimed at generating candidate classification criteria through the MAS score method described above. However, ALT levels were excluded owing to their close correlation with AST levels and a slightly lower statistical performance. They were replaced by neutrophil count or albumin level, depending on the model.

Table 3. Logistic regression model to assess association between the variables included in the final classification criteria and the experts' consensus of patients' classification as having or not having macrophage activation syndrome*

Explanatory variable	OR (95% CI)	*P*†
Ferritin >684 ng/ml	>999.999 (40.6−>999.999)	<0.0001
Platelet count ≤181 × 10^9/liter	237.0 (18.2−>999.999)	<0.0001
Triglycerides >156 mg/dl	18.3 (2.0–163.9)	0.009

Aspartate aminotransferase >48 units/liter	10.0 (1.3–78.4)	0.029

* The experts' consensus on patients' classification as having or not having macrophage activation syndrome (from the web-based process) was the dependent variable. Complete data were available on 227 patients. The area under the receiver operating characteristic curve of the model was 0.99. OR = odds ratio; 95% CI = 95% confidence interval.
† By likelihood ratio test.

Candidate classification criteria sets. Of the 982 sets of criteria tested, 45 were retained for further evaluation at the consensus conference. Of these, 37 (20 generated through the combination of criteria approach and 17 obtained with the MAS score method) were represented by criteria that met the statistical requirements described in Methods, and 8 were criteria derived from the literature. The statistical performance of the 20 best candidate criteria is presented in Supplementary Table 1 (on the *Arthritis & Rheumatology* web site at http://onlinelibrary.wiley.com/doi/10.1002/art.39332/abstract). The definition of and statistics on all 982 criteria tested are available from the corresponding author upon request.

Final classification criteria selected at face-to-face conference. During the consensus conference, 7 voting sessions were held among the 28 experts until 3 top classification criteria sets remained (criteria nos. 466, 472, and 929; Supplementary Table 1). Notably, the same criteria were selected independently by the 2 nominal groups, confirming convergent validity of the selection process. After the last voting session, 82% consensus was reached on the final definition (criteria no. 472; Supplementary Table 1). A subsequent open face-to-face discussion among all experts led to the decision to include in the final definition the presence of fever as a mandatory criterion and the requirement that the patient should have known or suspected systemic JIA. The final classification criteria selected at the consensus conference are presented in Figure 2.

Association between final classification criteria and experts' web-based consensus evaluations. For this multivariable analysis, complete data were available on 227 patients. The logistic regression model to evaluate

which were the variables included in the final classification criteria that most influenced the experts' decision to classify a patient as having or not having MAS is presented in Table 3. All variables were independently correlated with the experts' diagnoses. However, the association was much stronger for ferritin and platelet count. The AUC of the model was 0.99.

Preliminary validation of the final criteria set. The evaluation of the ability of the new classification criteria to discriminate MAS from comparator conditions in the patient sample not included in the expert evaluations (n = 415 of 683) showed a sensitivity of 0.73, a specificity of 0.99, a positive predictive value of 97.4%, a negative predictive value of 85.9%, an AUC of 0.86, and a kappa value for agreement between the diagnosis yielded by the criteria and the diagnosis made by the treating physician of 0.76.

Discussion

Using a consensus process as well as a statistical approach, we have developed a new set of classification criteria for MAS complicating systemic JIA (Figure 2). Because the criteria were established against comparison samples composed of patients with either a rheumatologic condition (active systemic JIA without evidence of MAS) or a nonrheumatologic condition (systemic infection), they may be of interest to a specialists in a range of disciplines.

The classification criteria include only laboratory variables and no clinical manifestations, with the exception of fever. This choice is in accordance with the common view that suspicion of MAS is most commonly raised by detection of subtle laboratory alterations, whereas clinical symptoms are often delayed and/or similar to those observed in other conditions (28). In a previous analysis of the MAS sample included in the present study, we found that 4 of the 5 laboratory tests that are part of the criteria (ferritin, platelet count, AST, and triglycerides) were among the parameters that showed a change of >50% between the last visit before the onset of MAS and the onset of MAS (16). In the same study, ferritin levels exhibited the largest change over time, which underscores the major importance of this feature in MAS detection and supports its use as a mandatory criterion. The key value of ferritin in the classification of MAS was corroborated by the observation that it was the parameter that had the greatest influence on the experts' classification of patients as having or not having MAS (Table 3).

Although the presence of fever did not enable discrimination between MAS and comparator illnesses as it was found in all or nearly all patients in each sample, the expert panel considered fever a prerequisite for the classification of MAS. The cardinal diagnostic role of fever is substantiated by the observation that it was the mostly highly ranked clinical feature identified in the Delphi survey (27). Unfortunately, we lacked reliable information on the pattern of fever in the 3 patient groups. However, it is generally accepted that the onset of MAS is heralded by a shift from the high-spiking intermittent pattern typical of active systemic JIA to a continuous nonremitting pattern (3,4,29).

The detection of macrophage hemophagocytosis in bone marrow biopsy specimens or aspirates or reticuloendothelial organ biopsy specimens is another frequent and characteristic feature of MAS. However, because hemophagocytosis is often absent during the early stages of MAS (18,19) and its demonstration requires an invasive procedure, the expert panel deemed it not necessary for the classification of systemic JIA–associated MAS. Notably, the demonstration of hemophagocytosis is not mandatory in either the HLH-2004 or the preliminary MAS diagnostic guidelines (24,25).

Although possibly useful for diagnostic purposes, the classification criteria are primarily intended for use in clinical trials and research studies. The criteria exhibited high accuracy and face/content validity in consensus and statistical evaluations, but it should be taken into account that they were developed using expert consensus as the gold standard. It also should be noted that the experts were asked to differentiate MAS from non-MAS conditions by reviewing the clinical features and laboratory values recorded at a single point in time (i.e., at disease onset), and were unaware of the patient's clinical course, laboratory values over time, response to treatment, or outcome. This information was, however, available to the treating physician, who made the original diagnosis in the clinical setting. This disparity in the available information may partially explain the high proportion of patients who were diagnosed by the treating physician as having MAS but classified by the experts as not having MAS (47 of 161; 29.2%). It is conceivable that because the experts were provided with only the information relevant to the development of the criteria, they tended to confirm the diagnosis of MAS only in straightforward and unambiguous cases.

It is therefore important to emphasize that the classification criteria may not capture all instances of MAS seen in the routine clinical setting, particularly those with subtle onset or incomplete clinical expression. Notably, of the 47 patients for whom the treating physician's diagnosis of MAS was not confirmed by the experts, 30 (63.8%) also did not meet the final classification criteria, 11 (23.4%) could not be assessed due to lack of data on the laboratory variables needed to apply the criteria, and only 6 (12.8%)

were classified as having MAS according to the final classification criteria. In addition, only 18 (46.6%) of the 37 patients for whom the experts could not agree on the diagnosis were classified as having MAS according to the final classification criteria. These findings underscore the consistency of the experts' evaluations and support the validity of the final classification criteria.

The fact that the cutoff values for platelet count and fibrinogen level included in the criteria are within the normal range of routine laboratory assessments may be regarded as clinically implausible. The same may apply to the cutoffs for AST and triglycerides, which are only slightly above the upper limits of normal. However, it is widely recognized that children with active systemic JIA often have increased platelet counts (e.g., $>600 - 800 \times 10^9$/liter) as well as elevated fibrinogen levels (e.g., >500–600 mg/dl) as part of the underlying inflammatory process (30,31). Thus, a paradoxically normal platelet count or fibrinogen level in the setting of otherwise prominent systemic inflammation may raise the suspicion of MAS (16,28). Because the levels of serum transaminases and triglycerides are generally normal in children with systemic JIA who do not have other coexistent pathologic conditions (e.g., infectious hepatitis or familial hyperlipidemia), their simple increase above the upper normal limits, combined with the other clinical and laboratory parameters included in the criteria, may be sufficient to herald the occurrence of MAS. This fits with the real-world patient data used in these studies to establish cutoff values that distinguish between children with JIA who have MAS and those who do not have MAS.

A secondary objective of the present project was analysis of the role of change in laboratory findings over time in the detection of MAS. However, this exercise was performed only for descriptive purposes, i.e., to identify and rank the laboratory parameters for which change over time was deemed by the experts as most important or useful for early detection of MAS. Because serial laboratory results were available for patients with MAS but not for the comparator groups, we could not establish the threshold level of change in each parameter that had the greatest sensitivity and specificity for the diagnosis of MAS. This precluded the ability to incorporate the change in laboratory values over time in the classification criteria. Due to space constraints, this analysis is reported in a separate manuscript (32).

Recently there have been several reports, from randomized controlled clinical trials and from postmarketing experience, of MAS occurring in patients with systemic JIA being treated with the cytokine blockers canakinumab and tocilizumab (33–35). Because these agents inhibit the biologic effects of IL-1 and IL-6, respectively, which are among the proinflammatory cytokines involved in the physiopathology of MAS (11,36), it is conceivable that MAS episodes developing during treatment with these biologic agents may occur in the absence of fever or some of the typical laboratory abnormalities of the syndrome. Clinical symptoms in patients with systemic JIA–associated MAS receiving tocilizumab were found to be milder than those in patients not receiving this treatment (37). Preliminary analyses in patients who developed MAS while receiving tocilizumab or canakinumab have shown that a few cases did not meet the new criteria, due to the absence of fever or a peak ferritin level of <684 ng/ml (38,39). More data from real-world clinical practice are needed to establish whether the criteria should be refined to increase their power to identify MAS occurring during treatment with IL-1 and IL-6 inhibitors.

Our study should be interpreted in light of some potential caveats. Patient data were collected through retrospective review of clinical charts, and retrospective analysis is subject to missing and possibly erroneous data. However, because all patient profiles were reviewed by the experts and the diagnosis of MAS or non-MAS was confirmed only when a high level of consensus was reached, the impact of this potential limitation was likely minimized. Some important diagnostic parameters of MAS, such as sCD25 and sCD163 levels and NK cell activity, could not be assessed due to their unavailability in some of the patient samples. However, these biomarkers are not routinely assessed, nor are they timely, in most pediatric rheumatology centers.

In summary, we have developed a set of classification criteria for MAS complicating systemic JIA and provided preliminary evidence of their validity. These criteria will help standardize the design and conduct of future clinical trials and research studies and contribute to enhancing knowledge and awareness of the syndrome.

ABSTRACT

Background Rheumatic and musculoskeletal immune-related adverse events (irAEs) are observed in about 10% of patients with cancer receiving checkpoint inhibitors (CPIs). Given the recent emergence of these events and the lack of guidance for rheumatologists addressing them, a European League Against Rheumatism task force was convened to harmonise expert opinion regarding their identification and management.

Methods First, the group formulated research questions for a systematic literature review. Then, based on literature and using a consensus procedure, 4 overarching principles and 10 points to consider were developed.

Results The overarching principles defined the role of rheumatologists in the management of irAEs, highlighting the shared decision-making process between patients, oncologists and rheumatologists. The points to consider inform rheumatologists on the wide spectrum of musculoskeletal irAEs, not fulfilling usual classification criteria of rheumatic diseases, and their differential diagnoses. Early referral and facilitated access to rheumatologist are recommended, to document the target organ inflammation. Regarding therapeutic, three treatment escalations were defined: (1) local/systemic glucocorticoids if symptoms are not controlled by symptomatic treatment, then tapered to the lowest efficient dose, (2) conventional synthetic disease-modifying antirheumatic drugs, in case of inadequate response to glucocorticoids or for steroid sparing and (3) biological disease-modifying antirheumatic drugs, for severe or refractory irAEs. A warning has been made on severe myositis, a life-threatening situation, requiring high dose of glucocorticoids and close monitoring. For patients with pre-existing rheumatic disease, baseline immunosuppressive regimen should be kept at the lowest efficient dose before starting immunotherapies.

Conclusion These statements provide guidance on diagnosis and management of rheumatic irAEs and aim to support future international collaborations.

INTRODUCTION

Although the concept of immunotherapy in cancer is far from new, monoclonal antibodies targeting immunological checkpoints or 'checkpoint inhibitors' (CPIs) represent a growing class of agents across multiple tumour types and at all stages of disease. Agents targeting the T-cell cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) or the programmed cell death-(ligand) 1 (PD-1/PD-L1) coinhibitory receptors marked a turning point in the success of immunotherapeutic approaches.[1–3] By enhancing antitumour T-cell activity, unprecedented long-lasting tumour responses were observed in patients with unresectable or advanced metastatic disease.[4–7] The clinical value of these immune CPIs, as single agents or in combination, is being investigated in various solid tumours and haematological malignancies, and their use is expanding rapidly.[8] So far, the Food and Drug Administration and the European Medicines Agency approved seven immune checkpoint-blocking antibodies in selected cancers: one anti-CTLA-4 (ipilimumab), three anti-PD-1 (nivolumab, pembrolizumab and cemiplimab) and three anti-PD-L1 (atezolizumab, avelumab and durvalumab).

The T-cell activation induced by CPIs commonly promotes inflammatory or autoimmune-like side effects, known as immune-related adverse events (irAEs).[9] Compared with conventional cancer therapies, this spectrum of toxicities is unique and can affect any organ system, most frequently the skin, gastrointestinal tract, endocrine glands and lung. Among irAEs, specific rheumatic manifestations have been described rather rarely in randomised clinical trials, but are much more common in clinical practice. The clinical features of rheumatic irAEs have been described in a growing number of case series and reports.[10] However, despite the growing interest for irAEs among rheumatologists, evidence is lacking for the optimal diagnostic approach and the management of these patients in ways that also permit effective antitumour therapy to continue. According to a recent survey, a large proportion of

rheumatologists have limited experience and little confidence in managing rheumatic irAEs, highlighting the need for education and recommendations in this emerging condition.[11]

In 2017, the European Society for Medical Oncology developed clinical guidelines for the management of immune toxicities and mentioned the paucity of literature on management of rheumatic irAEs.[12] Three other consensus recommendations have been proposed by the Society for Immunotherapy of Cancer, the American Society of Clinical Oncology and The National Comprehensive Cancer Network, which among others included the management of inflammatory arthritis, polymyalgia rheumatica and myositis.[13–15] This European League Against Rheumatism initiative assembled international experts primarily from the rheumatology and immunology but also the oncology field with the explicit goal of generating the first set of recommendations for the diagnosis and the management of rheumatic irAEs arising as a direct consequence of CPI. Rheumatologists, but also in some countries internists and immunologists, have to play a pivotal role in developing with the oncologists a patient-centred approach to improve the management of rheumatic irAEs. While the initiative primarily set out to guide clinicians, it is noteworthy that there is limited and rapidly changing literature and that future additional studies can drastically change the profile for diagnosis and management. This area will be a continually evolving field; therefore, the accompanying comments may also serve as a framework for future longitudinal cohorts and/or clinical studies.

METHODS

After approval by the European League Against Rheumatism Executive Committee, an international task force was convened to develop points to consider for the diagnosis and the management of rheumatic irAEs due to cancer immunotherapy. Among these members, were 19 clinical experts from Europe and North America (14 rheumatologists including 2 delegates of the European League Against Rheumatism young rheumatologists' network EMEUNET, 2 internists and 3 oncologists), 1 clinical epidemiologist, 1 allied health professional and 2 patient representatives from the PARE network of patient research partners. The process adhered to the updated European League Against Rheumatism standardised operating procedures for the development of recommendations.[16]

In July 2018, the first meeting was convened in Zürich, Switzerland, to define the focus of the task force, identify the target population and the research questions for the systematic literature review (SLR). The SLR was performed by the research fellow (MK), with support from the clinical epidemiologist (AF) and a librarian (Catherine Weill), to identify relevant publications through December 2018. Based on the findings of the SLR, a first draft of points to consider including 12 items was prepared by the fellow (MK) and the two convenors (TS and XM).

SLR results were presented at a second meeting that was held in Zürich, Switzerland, in January 2019. Following the evaluation of literature and a group discussion of the first draft of propositions, the task force formulated overarching principles and consensus statements. Each proposal was then submitted to a voting process, requiring at least 75% of votes in the first ballot for each recommendation to be accepted. In case this threshold was not achieved, further discussion and textual changes were proposed for a second round, for which a 67% majority was required. Five members of the task force could not attend this second meeting, but they subsequently commented and voted on each statement by email. The level of evidence (LoE) and grade of recommendation was based on the Oxford Levels of Evidence.[17] After this second face-to-face meeting, members of the task force were asked to anonymously rate each item in an online survey, on a scale of 0 (absolutely disagree) to 10 (absolutely agree) to assess the level of agreement (LoA). Furthermore, the task force agreed on adding relevant references published between the SLR and the writing of this manuscript. The manuscript was reviewed and approved by all task force members and the European League Against Rheumatism Executive Committee before submission.

RESULTS

Systematic literature review

The literature search strategy and summary of results are detailed in online supplementary data. The first objective was to identify phase III clinical trials to assess the frequency and type of rheumatic and musculoskeletal diseases' (RMDs) complaints associated with CPI compared with the comparator group. The search was performed using Medline, Embase and the Cochrane Library, through December 2018. Among 630 references identified, 22 studies were selected for inclusion. The second objective was to obtain detailed information on rheumatic and musculoskeletal symptoms that have been described under CPI treatment. The third objective was to assess outcomes in patients with pre-existing autoimmune diseases. Therefore, relevant keywords relative to three key domains were used in Medline and Embase databases: immune CPIs, rheumatic and systemic diseases and adverse events. Abstracts from the last two European League Against Rheumatism and American College of Radiology meetings were included, combined with manual searches from references of the selected articles. From among 2156 references identified, 170 were included, including pharmacovigilance registries (n=5), case series (n=51) and case reports (n=114).

After group discussion of the results of the SLR, the consensus process was initiated and the full task force agreed on a final set of 4 overarching principles and 10 points to consider (table 1).

Overarching principles

A. Rheumatic and musculoskeletal immune-related adverse events can occur as manifestations in cancer patients receiving immunotherapy with checkpoint inhibitors (LoE na; LoA 9.6).

Analysis of phase III clinical trials revealed that arthralgia, arthritis, myalgia, myositis, dry mouth, musculoskeletal and back pain were reported in patients receiving CPI. However, their frequency was not significantly different to that of patients receiving chemotherapy or placebo.[5 18–38] Data from several series, both retrospective and prospective, reporting prevalences of rheumatic irAEs in real life, ranging from 1.5% to 22%, suggest that rheumatic irAEs are under-reported in clinical trials.[39–54] Of note, an heterogeneous definition of rheumatic irAEs may explain such wide interval. Many clinical trials do not report rheumatic irAEs (by disregarding of musculoskeletal/rheumatic events as a distinct organ system, even in the online supplementary data) or partially only report high-grade and/or frequent adverse events (ie, occurring in ≥10% of the patients). Therefore, the task force wanted to emphasise with this first principle that rheumatic and musculoskeletal manifestations are a relevant part of the broad spectrum of irAEs.

B. Management of rheumatic and musculoskeletal immune-related adverse events should be based on a shared decision-making process between patients, oncologists and rheumatologists (LoE na; LoA 9.5).

Ann Rheum Dis: first published as 10.1136/annrheumdis-2020-217139 on 23 April 2020. Downloaded from http://ard.bmj.com/ on February 3, 2023 by guest. Protected by copyright.

Table 1 Overarching principles and points to consider for the diagnosis and management of rheumatic irAEs

		LoE	GoR	LoA (0–10) mean (SD)
Overarching principles				
A.	Rheumatic and musculoskeletal immune-related adverse events can occur as manifestations in cancer patients receiving immunotherapy with checkpoint inhibitors.	n.a.	n.a.	9.6 (0.7)
B.	Management of rheumatic and musculoskeletal immune-related adverse events should be based on a shared decision-making process between patients, oncologists and rheumatologists.	n.a.	n.a.	9.5 (1.1)
C.	Rheumatologists should engage with oncologists to contribute to the inter-disciplinary care of patients presenting with musculoskeletal signs and symptoms.	n.a.	n.a.	9.1 (1.2)
D.	The role of rheumatologists is to assist oncologists in differential diagnosis and to relieve rheumatic and musculoskeletal symptoms to an acceptable level enabling patients to maintain effective cancer immunotherapy.	n.a.	n.a.	9.5 (0.9)
Points to consider				
1.	Rheumatologists should be aware of the wide spectrum of clinical presentations of rheumatic and/or systemic immune-related adverse events that often do not fulfil traditional classification criteria of RMDs.	4	C	9.5 (1.2)
2.	Oncologists should be encouraged to consult rheumatologists promptly for assessment when rheumatic musculoskeletal and systemic signs or symptoms are suspected due to immunotherapy, and rheumatologists should provide facilitated access for such patients.	5	D	9.4 (1.3)
3.	Metastases, paraneoplastic syndromes and unrelated rheumatic diseases should be considered as a potential differential diagnosis of rheumatic immune-related events. The comprehensive assessment should be focused on documenting evidence of target organ inflammation, and based on history, clinical features, laboratory tests, imaging and/or biopsy.	4	C	9.5 (0.9)
4.	In case of inefficacy of symptomatic treatment and depending on the disease severity, local and/or systemic glucocorticoids should be considered for immune-related rheumatic and systemic symptoms. Dose regimen and route of administration should be decided according to the clinical entity and activity. When improvement is achieved, systemic glucocorticoids should be tapered to the lowest effective dose to control the symptoms.	4	C	9.4 (1)
5.	csDMARD should be considered in patients with insufficient response to acceptable dose of glucocorticoids or requiring glucocorticoid-sparing.	4	C	9 (1.2)
6.	For patients experiencing severe immune-related rheumatic and systemic immune-related adverse events or with insufficient response to csDMARD, bDMARD may be considered, with TNF or IL-6 inhibitors being the preferred options for inflammatory arthritis.	4	C	8.8 (1.2)
7.	The decision to hold or to continue the cancer immunotherapy should be based on the severity of rheumatic immune-related adverse events, the extent of required immunosuppressive regimen, the tumour response and its duration, as well as the future oncology treatment plan, in a shared decision with the patient.	5	D	9.4 (1)
8.	Myositis may be a severe condition. Immunotherapy withdrawal needs to be discussed. In the presence of life-threatening manifestations (bulbar symptoms (dysphagia, dysarthria, dysphonia), dyspnoea and myocarditis), high dose of glucocorticoids, IVIg and/or plasma exchange should be considered; immunotherapy withdrawal is always necessary.	4	C	8.9 (1.2)
9.	A pre-existing autoimmune rheumatic and/or systemic disease should not preclude the use of cancer immunotherapy. Baseline immunosuppressive regimen should be kept at the lowest dose possible (for glucocorticoids, below 10 mg prednisone per day if possible). However, many patients may have a flare of the underlying condition and/or immune-related adverse events, requiring the use of glucocorticoids and/or DMARDs.	4	C	9 (1.3)
10.	Before initiation of cancer immunotherapy, there is no indication to test every patient for the presence of autoantibodies. In the case of unexplained rheumatic, musculoskeletal or systemic symptoms, a complete rheumatological assessment should be performed.	5	D	9 (1.3)

GoR: A: based on consistent level 1 studies; B: based on consistent level 2 or 3 studies or extrapolations from level 1 studies; C: based on level 4 studies or extrapolations from level 2 or 3 studies; D: based on level 5 studies or on troublingly inconsistent or inconclusive studies of any level.
LoE: 1a: systematic review of RCTs; 1b: individual RCT; 2a: systematic review of cohort studies; 2b: individual cohort study (including low-quality RCT); 3a: systematic review of case–control studies; 3b: individual case–control study; 4: case-series (and poor quality cohort and case–control studies); 5: expert opinion without explicit critical appraisal, or based on physiology, bench research or 'first principles'.
bDMARD, biological disease-modifying antirheumatic drug; csDMARD, conventional synthetic disease-modifying antirheumatic drug; DMARD, disease-modifying antirheumatic drug; GoR, grade of recommendation; IL-6, interleukin 6; irAEs, immune-related adverse events; IVIg, intravenous immunoglobulin; LoA, level of agreement; LoE, level of evidence; RCT, randomised clinical trial; RMD, rheumatic and musculoskeletal disease; TNF, tumour necrosis factor.

Rheumatic and musculoskeletal irAEs occur in a context of cancer; therefore, a dialogue between rheumatologists and oncologists is important to balance the harm and risk of oncology treatment and immunosuppressive drugs. The most important stakeholder is the patient. Shared decision between a patient and his/her rheumatologist is a fundamental principle of RMDs management, as illustrated by its representation as an overarching principle in several European League Against Rheumatism recommendations.[55–57] Because evidence-based data for irAEs management are limited, and irAEs can have a large impact on the quality of life, patient's preferences and discussions concerning risks and benefits of each treatment option are even more important.

C. Rheumatologists should engage with oncologists to contribute to the inter-disciplinary care of patients presenting with musculoskeletal signs and symptoms (LoE na; LoA 9.1).

IrAEs may affect any organ system including the rheumatic and musculoskeletal system. Some patients may even experience multiple organ toxicities in sequence or concurrently. The importance of developing a local multidisciplinary network of oncologists and specialists of all organ system potentially involved in the management of irAEs has been recently highlighted.[58 59] Rheumatologists should actively engage in these local multidisciplinary networks as valuable members due to their knowledge of clinical immunology, their expertise in multiorgan autoimmune disease and their long-standing

Ann Rheum Dis: first published as 10.1136/annrheumdis-2020-217139 on 23 April 2020. Downloaded from http://ard.bmj.com/ on February 3, 2023 by guest. Protected by copyright.

experience with the use of immunosuppressive drugs and biological therapies.[60] This engagement should also include efforts aimed at improving patient education before or when starting cancer immunotherapy, to prevent delay in diagnosis when rheumatic or musculoskeletal side effects occur. Patients have reported that they were informed about other immune-related side effects more than rheumatic or musculoskeletal symptoms.[61] Furthermore, since the rheumatic and the cancer disease both induce high impact on the patient's life, even when independently considered and when disease activity is controlled (ie, fatigue, pain, functional impairments, emotional problems, secondary effects of the treatments), the value of an interdisciplinary collaboration between the rheumatologist and the oncologist is worthwhile.

D. The role of rheumatologists is to assist oncologists in establishing the diagnosis and to relieve rheumatic and musculoskeletal symptoms to an acceptable level enabling patients to maintain effective cancer immunotherapy (LoE na; LoA 9.5).

This principle aimed to better define the role of rheumatologists as oncologists' partners based on the clinical experience of the task force members. Once a patient with cancer receiving immunotherapy is referred for evaluation of rheumatic or musculoskeletal symptoms, the rheumatologist should consider several potential aetiologies: tumour progression, paraneoplastic syndromes, non-rheumatic events (ie, viral infection, thrombosis, endocrine abnormality), all already considered by the referring oncologist, or rheumatic/systemic irAE or immune non-related adverse events. This aspect of differential diagnosis is also described in more detail in recommendation 3. Once a rheumatic irAE is diagnosed, the supervising rheumatologist should propose an appropriate treatment to relieve patient's symptoms to an acceptable level with the objective of maintaining quality of life and permitting continuation of effective cancer immunotherapy, if this is recommended by the oncologist. This treatment goal is different to classic rheumatic entities, in which usually remission is the targeted treatment outcome.

Points to consider

1. Rheumatologists should be aware of the wide spectrum of clinical presentations of rheumatic and/or systemic immune-related adverse events that often do not fulfil traditional classification criteria of RMDs (LoE 4; LoA 9.5).

While arthralgia and myalgia were the most commonly reported rheumatic irAEs in clinical trials, numerous case series and reports have captured a broader spectrum of de novo rheumatic and systemic manifestations that can occur with cancer immunotherapy.[62–64] Polymyalgia rheumatica (PMR)-like syndromes and inflammatory arthritis syndromes are two of the major clinical presentations encountered.[39–41 48 65 66] PMR-like manifestation occurred with a median exposure time to CPI of 60 days, but also much later (IQR 24–210 days). Exposure time to CPI was generally longer for patients experiencing inflammatory arthritis (median 120 days, IQR 48–262 days). In addition, a variety of other rheumatic syndromes have been reported. These include arthralgia; monoarthritis, oligoarthritis or polyarthritis; reactive arthritis; psoriatic arthritis (PsA); remitting seronegative symmetrical synovitis with pitting oedema (RS3PE); tenosynovitis; enthesitis; non-inflammatory musculoskeletal conditions and osteoarthritis.[41 44 46 51 66–77] Importantly, autoantibodies are often absent. In arthritis, only a few patients are positive for rheumatoid factor (RF; n=20, range 18–246 UI/mL) and/or anti-citrullinated peptide antibodies (ACPAs; n=14, range 18–614 U/mL).[78] Instead, positivity of antinuclear antibodies (ANAs) is observed, but often at a low titre (range 1:80 to 1:3200, one patient with ANA 1:12 800 and only 35 patients with ANA >1:160). Similarly, acute phase reactants may be normal in some patients with PMR-like presentations.[41] Overall, around 20% of patients fulfilled classification criteria of rheumatoid arthritis (RA) (55/271) or PMR (11/52). This percentage was higher (55%) for PsA (6/11), as well as in a recent series of PMR-like syndrome (37/49; 75%).[79] The first observation of recurrent pseudogout flares 7 to 10 days after each nivolumab infusion has been recently reported.[80]

Several cases of myositis have been reported, with frequent limb-girdle myalgia and weakness that may mimic a PMR-like condition.[81–83] Because it represents a potentially life-threatening complication, the task force decided to formulate a dedicated recommendation on myositis (*recommendation 8*).

Among systemic manifestations, sicca syndrome has been described early on, presenting mainly with dry mouth, and possible associated neurological symptoms in a few patients.[40 48 65 66 84–87] Two major studies on CPI-induced sicca syndrome were published in 2019 and therefore included in this manuscript. The ImmunoCancer International Registry reported on 26 patients experiencing CPI-associated sicca syndrome. This mainly included men, with frequent organ-specific autoimmune manifestations but lower prevalence of autoantibodies (52% ANA, 20% Ro/SS-A, 9% RF, 8% La/SS-B) in comparison with classical Sjögren's syndrome.[88] Interestingly, a predominant T-cell infiltrate with acinar destruction has been reported in salivary glands, distinct from the histological profile of idiopathic primary Sjögren's syndrome. Authors hypothesise that CPI therapy may break immune tolerance locally leading to the activation of cytotoxic T cells damaging the salivary epithelium.[89]

Other systemic manifestations have been described, including sarcoidosis or sarcoid-like reactions.[90–93] The diagnosis is usually suspected through imaging when new hilar lymphadenopathy or pulmonary nodules are detected in imaging, requiring biopsy. Half of patients experienced cutaneous manifestations (nodules, rash), and some patients had cough/dyspnoea (29%) and arthralgia/arthritis (18%). Uveitis, parotitis, hypercalcaemia and neurological symptoms are rarely reported. Some patients experienced systemic sclerosis or scleroderma-like reactions, all presenting with skin thickening, but only one with new-onset Raynaud's phenomenon.[48 94–96] None tested positive for specific autoantibodies. Since PD-1-deficient mice spontaneously developed lupus-like autoimmune diseases with arthritis and glomerulonephritis, such clinical phenotypes could be expected in patients treated with anti PD-(L)1 agents, but are not observed. A few cases of lupus-like cutaneous reaction and one Jaccoud arthropathy have yet been reported with anti-PD-1 agents, and only one lupus-like nephritis was attributed to anti-CTLA-4 treatment.[97–102]

All vessel-sized vasculitis (eg, large, medium and small vessels) with various clinical manifestations, including purpura, digital necrosis arthralgia, arthritis, myalgia, fever, fatigue and abdominal pain have also been reported.[40 48 84 103–113] Of note, ANA, antineutrophil cytoplasmic antibodies (ANCAs), cryoglobulin and RF were rarely positive. Analysis of the WHO pharmacovigilance database revealed that temporal arteritis (n=16) was particularly over-reported with ipilimumab monotherapy treatment.[114] The first case of granulomatosis with polyangiitis with a high anti-PR3 ANCA titre was reported in 2019.[115]

Recently, patients experiencing rapid bone loss with CPI leading to multiple fractures were reported, raising the question of a potential influence of immune activation on bone metabolism.[116]

Ann Rheum Dis: first published as 10.1136/annrheumdis-2020-217139 on 23 April 2020. Downloaded from http://ard.bmj.com/ on February 3, 2023 by guest. Protected by copyright.

Importantly, rheumatic and/or systemic irAEs may occur across all classes of CPI, most frequently and severely with combination treatments and may be associated with other organ-specific irAEs.

2. Oncologists should be encouraged to consult rheumatologists promptly for assessment when rheumatic musculoskeletal and systemic signs or symptoms are suspected due to immunotherapy, and rheumatologists should provide facilitated access for such patients (LoE 5; LoA 9.4).

The data that are available regarding the process of referral to a rheumatologist suggests that this is not widely done and might lead to delay in diagnosis. In one series, only 4 out of 12 patients experiencing rheumatic irAEs were reviewed by rheumatologists.[43] One cohort reported an average of 9.5±9.3 days between the counselling request and the first rheumatologist visit and 2.5±4.4 months from the start of arthralgias to the confirmation of synovitis.[67] Two other series reported a median of 34 days (range 16–210 days) and 7 days (range 1–57 days) before a rheumatology appointment.[66 117] Rheumatic side effects of CPI appear underappreciated, which probably delays proper assessment and treatment. However, as mentioned in the overarching principles, a prompt rheumatological evaluation should support rapid shared treatment decision to relieve patient symptoms, maintain a good quality of life and allow pursuing an effective cancer immunotherapy.

Currently, algorithms for irAEs management are based on the severity/grade of the irAE according to the Common Terminology Criteria for Adverse Events (CTCAE v5.0). The first international guidelines recommended referral to a rheumatologist in the case of severe symptoms not responding to glucocorticoids (grade 3). Subsequently, prompt referral was proposed as soon as the patient experienced moderate pain associated with signs of inflammation (grade 2).[12–14] While CTCAE grading is routine for oncologists, and a requirement for clinical trials, rheumatologists are less familiar with this grading which do not accurately reflect the spectrum or severity of rheumatic or systemic manifestations (online supplementary table S1). Accordingly, the task force decided not to use the CTCAE grading system to prioritise referral but instead to recommend prompt assessment, ideally before starting glucocorticoids. For this purpose, rheumatologists should be encouraged to offer facilitated access since they may be able to avoid systemic glucocorticoids or use lower dose than oncologists to manage rheumatic toxicities.

3. Metastases, paraneoplastic syndromes and unrelated rheumatic diseases should be considered as a potential differential diagnosis of rheumatic immune-related events. The comprehensive assessment should be focused on documenting evidence of target organ inflammation, and based on history, clinical features, laboratory tests, imaging and/or biopsy (LoE 4; LoA 9.5).

The first part of this statement has previously highlighted the overarching principle of defining the role of the rheumatologist (*overarching principle D*). While delaying the diagnosis of irAEs and its adequate treatment may result in a worse prognosis regarding both CPI adherence and immune-mediated tissue/organ destruction, focusing only on irAEs without considering other differential diagnoses may also be inappropriate. CPIs are commonly administered to patients with advanced cancer, and so new rheumatic/musculoskeletal symptoms must raise suspicion of cancer progression, as well as the lack of improvement of inflammatory arthritis with glucocorticoids (ie, possibility of metastases or paraneoplastic syndrome).[118 119] Advanced imaging, such as CT scan, MRI, bone scintigraphy or positron emission tomography-CT, may be helpful in arriving at such a diagnosis. The diagnosis of irAEs versus metastasis may become even more challenging as non-malignant resorptive lesions have recently been described, which can mimic metastases.[116] Pulmonary sarcoidosis-like lesions may also be first considered as tumour progression.

Immunological toxicities may also manifest as paraneoplastic syndromes. Current literature covers mainly paraneoplastic neurological syndromes with few published data regarding paraneoplastic rheumatic syndromes.[120 121] However, based on the clinical experience of task force members, the group agreed to include paraneoplastic syndromes in the differential diagnosis of rheumatic irAEs to inform clinicians that they may encounter newly and not pre-existing paraneoplastic syndromes following CPI therapy, notably hypertrophic osteoarthropathy. RS3PE and dermatomyositis were also reported, either as paraneoplastic syndromes or induced by CPI therapy, but one may not be able to make the distinction when appearing under CPI therapy.

The term ‘unrelated rheumatic diseases’ covers manifestations for which the causal link with cancer immunotherapy is not obvious, such as shoulder tendinitis, lateral epicondylitis, non-inflammatory back pain or complex regional pain syndrome. The task force agrees that it may be difficult to establish when a specific rheumatic feature can be considered related or unrelated to the administration of CPI. Using the adverse drug reaction probability score (Naranjo scale) may help to assess the causal link with CPI therapy.

The task force proposes that the key objective of the diagnostic work-up is to document evidence of target organ inflammation. By adopting the term target organ inflammation, the task force wants to emphasise that priority for the supervising rheumatologist is not only to search for joint inflammation but also to document evidence of any organ inflammation according to the symptoms presented (muscle, fascia, vessels, heart, lung, skin, endocrine glands, salivary glands, etc), either clinically or preferably by using appropriate laboratory tests, imaging and tissue biopsy.

Tissue diagnosis should be decided on a case-by-case basis, based on the type and severity of rheumatic irAE, when other supportive information would not be sufficient to make a clinical decision in terms of therapy. Notably, histopathological data may be frequently indicated in patients presenting with vasculitis, sarcoidosis and myositis, but should not interfere with starting treatment, particularly with myositis or patients presenting with life-threatening irAE. On the other hand, synovial biopsies will not change the acute management of inflammatory arthritis. They may provide insights into targeted therapies with glucocorticoid saving approaches, but are not recommended for daily practice.

4. In case of inefficacy of symptomatic treatment and depending on the disease severity, local and/or systemic glucocorticoids should be considered for immune-related rheumatic and systemic symptoms. Dose regimen and route of administration should be decided according to the clinical entity and activity. When improvement is achieved, systemic glucocorticoids should be tapered to the lowest effective dose to control the symptoms (LoE 4; LoA 9.4).

In the absence of contraindications, symptomatic treatment including non-steroidal anti-inflammatory drugs and/or analgesics should be the initial treatment for mild-to-moderate rheumatic manifestations. There are no data on the efficacy of symptomatic therapies in the context of systemic manifestations. An anti-inflammatory effect of these drugs can be expected within several hours or a few days. Additionally, intra-articular glucocorticoids should be considered in the context of monoarthritis

Ann Rheum Dis: first published as 10.1136/annrheumdis-2020-217139 on 23 April 2020. Downloaded from http://ard.bmj.com/ on February 3, 2023 by guest. Protected by copyright.

or oligoarthritis, combined with an analysis of the synovial fluid, whenever possible, to rule out differential diagnoses such as infection, osteoarthritis or crystals.[40–42 48 66 67 75–77 122–126] If symptomatic treatment is insufficient and tissue inflammation is still evident, systemic glucocorticoids should be considered for both immune-related rheumatic and systemic symptoms. Overall, systemic glucocorticoids were used for 224/296 patients (76%) with arthritis[39–44 46 48 51 52 65–74 76–78 83 116 122 123 125–143] with a median dosage of 20 mg/day, for 37/65 patients (57%) with sicca syndrome[39 40 65 66 85–89] with a median dosage of 40 mg/day (16 patients for sicca symptoms, 15 patients for systemic manifestations or associated arthritis, 6 patients for sicca symptoms and associated other irAE), for 22/29 patients (76%) with vasculitis[48 84 103–106 108–112 144–150] with a median initial dosage of 60 mg/day, for 15/33 patients (45%) with sarcoidosis[39 44 91–93 151–158] with a median initial dosage of 55 mg/day, for 7/7 patients (100%) with scleroderma[48 94–96] with an initial dosage of 1 mg/kg/day and for 4/13 patients (31%) with lupus.[98–101] Subacute cutaneous lupus was mainly treated with topical steroids.[97] Treatment of patients with myositis is reported in a separate statement (*point to consider 8*).

So far, there are reassuring data regarding the use of glucocorticoids for irAE management.[159 160] For rheumatic irAEs, patients receiving glucocorticoids equivalent to 10 mg/day of prednisolone for 6 weeks concurrent to anti-PD1 therapy had a similar antitumour response.[77] However, recent preclinical data point out that glucocorticoids markedly impair the activation and the killing ability of tumour-infiltrating lymphocytes.[161] Because of concerns of glucocorticoids on antitumour responses, the task force did not recommend using methylprednisolone pulses or high-dose oral glucocorticoids in the absence of life-threatening complications and myositis, even in severe presentations, and favoured the concept of glucocorticoid sparing where rheumatologists have extensive experience with alternative options. Furthermore, the task force members recommended tapering glucocorticoids to the lowest effective dose within weeks or as soon as improvement is achieved was desirable. The objective of reaching a dose less than or equal to 10 mg/day of equivalent prednisone was considered as an acceptable target dose. This target dose as maintenance therapy is based on current preclinical and retrospective clinical data,[161–163] and higher than the one recommended for the main classical RMDs (online supplementary table S2).

5. csDMARD should be considered in patients with insufficient response to acceptable dose of glucocorticoids or requiring glucocorticoid-sparing (LoE 4; LoA 9).

In case of active rheumatic irAE requiring dose of glucocorticoids higher than 10 mg/day of equivalent prednisone, conventional synthetic disease-modifying antirheumatic drug (csDMARD) should be considered. Several csDMARDs have been used as second-line therapy in the case of an insufficient response to glucocorticoids or for use as steroid sparing agents. So far, no specific biological disease-modifying antirheumatic drug has proven superiority. For the various types of arthritis in cases reported, methotrexate was the most frequently drug prescribed, followed by hydroxychloroquine then sulfasalazine, either as monotherapy or in combination.[39–41 43 44 48 51 52 65–67 69 70 75–78 122 123 125 128 131 132 134 140–142 164 165] Of note, no safety issues were described regarding long-term use of methotrexate associated with CPI in a few patients, with a median follow-up of over 1 year.[67] It is noteworthy that a higher proportion of hypersensitivity reactions were reported with sulfasalazine in the context of CPI-induced inflammatory arthritis, suggesting caution to its use in those situations.[165] One case series reported the initiation of hydroxychloroquine prior to glucocorticoids, limiting glucocorticoid exposure, which would deserve further evaluation.[166] The use of csDMARDs has not been described for patients with CPI-induced sicca syndrome. Two patients received hydroxychloroquine and one the combination of hydroxychloroquine and methotrexate for cutaneous leucocytoclastic vasculitis.[103] One patient with granulomatosis with polyangiitis was treated with oral cyclophosphamide.[105] For other systemic manifestations, hydroxychloroquine was safely prescribed for patients with CPI-induced lupus and scleroderma and in one patient with sarcoidosis.[48 95–100 157] Four patients with scleroderma-like syndromes received mycophenolate mofetil.[48 94 96] Among them, two also received intravenous immunoglobulin. Finally, two patients with neurosarcoidosis were successfully treated with methotrexate after an infusion reaction to infliximab.[92 93]

6. For patients experiencing severe rheumatic and systemic immune-related adverse events or with insufficient response to csDMARD, bDMARD may be considered, with TNF or IL-6 inhibitors being the preferred options for inflammatory arthritis (LoE 4; LoA 8.8).

Gastroenterologists have safely and successfully administered infliximab for patients with severe CPI-induced colitis who had an insufficient response to glucocorticoids.[167 168] Based on these data, tumour necrosis factor (TNF) inhibitors (infliximab prevailing on etanercept and adalimumab) have been reported for severe and refractory inflammatory arthritis.[65 66 116 123 138] However, while patients experiencing colitis required one or two infliximab infusions, patients with arthritis may require long-term administration of TNF inhibitors, which is an important difference of unclear clinical significance at this time. A recent study reported that antitumour responses were not adversely affected in patients treated with TNF inhibitors, with a median follow-up of 9 months, but further data are needed.[169] Preclinical data support the use of TNF inhibitors, since infliximab only had a minor influence on T-cell activation and the killing ability of tumour-infiltrating lymphocytes, whereas even low doses of glucocorticoids markedly impaired this antitumour activity.[161] Furthermore, a synergistic effect of TNF inhibitors with CPI has been demonstrated in mouse models.[170 171] A phase I investigator-initiated trial (TICIMEL, NCT03293784) is currently testing the safety of this combined approach (double immunotherapy plus TNF inhibitor) in patients with melanoma. Results of this study will likely inform the management of rheumatic irAEs. The use of infliximab was also reported in two patients with neurosarcoidosis.[92 93]

There are also several observations in patients with CPI-induced inflammatory arthritis treated with tocilizumab.[48 52 68 83] Notably, one patient responded to tocilizumab after infliximab failure.[52]

Regarding interleukin 17 blockade, the use of secukinumab has been reported in a patient with mismatch-repair-deficient metastatic colon cancer and a previous history of Crohn's disease who experienced colitis, severe psoriatic rash and arthralgia.[172] While providing a dramatic relief of the immune-related skin, rheumatic and gastrointestinal side effects, subsequent tumour progression was observed. A second recent publication described the complete resolution of pembrolizumab-induced psoriasiform eruption with secukinumab in a patient with melanoma, without impact on tumour response.[173] Due to limited data and concerns about interleukin 17 inhibition on CPI efficacy, the task force agreed not to recommend interleukin 17 blockade for inflammatory arthritis.

Ann Rheum Dis: first published as 10.1136/annrheumdis-2020-217139 on 23 April 2020. Downloaded from http://ard.bmj.com/ on February 3, 2023 by guest. Protected by copyright.

For mechanistic reasons, abatacept should also not be considered for the treatment of CPI-induced rheumatic and systemic diseases, owing to the hypothetical risk of antagonising antitumour responses of CPI. However, one may consider its use in cases of life-threatening conditions, as discussed in the statement for myositis (*point to consider 8*).

One patient with neuro-Sjögren's syndrome was successfully treated with rituximab after intravenous pulses of methylprednisolone, immunoglobulins and one dose of cyclophosphamide.[87] Rituximab was also used in one patient with acral vasculitis without improvement and the need of surgical amputation.[105]

7. The decision to hold or to continue the cancer immunotherapy should be based on the severity of rheumatic immune-related adverse events, the extent of required immunosuppressive regimen, the tumour response and its duration, as well as the future oncology treatment plan, in a shared decision with the patient (LoE 5; LoA 9.4).

Currently, decisions regarding CPI and immunosuppressive regimens vary from institution to institution according to local practice, with no randomised trials to provide evidence in choosing between holding CPI and/or introducing an immunosuppressive regimen. Overall, the SLR revealed that CPIs were discontinued in 25% of patients experiencing inflammatory arthritis, 61% of patients with sicca syndrome (a discontinuation of CPI often due to another associated irAE), 80% of patients with vasculitis, 64% of patients with sarcoidosis, 75% of patients with scleroderma and 78% of patients with lupus. It is noteworthy that several studies reported ongoing clinical benefit in patients who discontinue their cancer immunotherapy for irAEs.[7 174 175] Well-designed prospective trials will be required help to clarify the optimal immunosuppressive regimens.

8. Myositis may be a severe condition. Immunotherapy withdrawal needs to be discussed. In the presence of life-threatening manifestations (bulbar symptoms (dysphagia, dysarthria, dysphonia), dyspnoea and myocarditis), high dose of glucocorticoids, IVIg and/or plasma exchange should be considered; immunotherapy withdrawal is always necessary (LoE 4; LoA 8.9).

Myositis belongs to the spectrum of potentially fatal toxicity associated with CPI, since it is frequently associated with myocarditis and/or myasthenia gravis.[176–178] Notably, it generally occurs very early after CPI initiation, often within the first month of treatment (median exposure time of 25 days, IQR 25–45 days). Proximal weakness and myalgia are the major symptoms, which can mimic a PMR-like condition.[81] Therefore, a high awareness for myositis is needed among rheumatologists with measurement of creatine kinase (CK) since increased CKs are seen in the majority of patients with myositis (median of 2650 IU/L, ranging from 335 to 20 270 IU/L).[48 77 81–83 100 117 179–207] Of note, CK levels are usually within the normal range in patients presenting with myalgia.[42 83] Ptosis and diplopia are also commonly reported and may be related to associated myasthenia gravis.[81 82 100 117 184 185 189 191 192 195 197 198 204 205 208–210] Of note, some patients present with dropped head syndrome.[82 198 211] Importantly, one should search for the presence of life-threatening manifestations, including dyspnoea, palpitations, chest pain or syncope, which should alert on a possible concurrent myocarditis.[39 48 77 81–83 117 177–179 182 184 185 187 190 193 200 207 211–215] Of note, an increased risk of death in patients experiencing CPI-related myositis has been observed compared with patients with idiopathic inflammatory myositis (around 20% vs less than 10%).[177 216] This increased mortality rate seems to be related to the development of myocarditis. While there is no standardised assessment of myocarditis in large series of idiopathic inflammatory myopathy, signs of myocardial inflammation cardiac has been reported on magnetic resonance tomography in more than 60% of such patients,[217] which argue that myocarditis belong to the myositis clinical spectrum and does not represent a different concomitant irAE. Therefore, cardiac evaluation must be systematic for any patient with myositis or suspected myositis. It includes cardiac troponin (troponin T is less specific than troponin I in case of associated skeletal muscle diseases) and electrocardiography. In case of clinical syndrome associated with myocarditis and/or increase cardiac troponin level and/or electrocardiography, a cardiac MRI is necessary.[218] Of note, normal cardiac enzyme cannot always rule out the possibility of myocarditis. Furthermore, the presence of bulbar symptoms (dysphagia, dysarthria, dysphonia) and/or respiratory failure may be related to myositis or associated myasthenia gravis encountered in 12.5% of patients (57/454 cases reported).[82 83 100 177 178 186 188 189 192 195 203 204 208 211 212] Of note, the majority of patients will not have a typical skin rash of dermatomyositis, only reported in a few patients.[199 201 219]

Myositis-associated autoantibodies are mostly negative, though cases with positive ANA, antistriated antibodies, anti-PM/Scl, anti-SM, anti-TIF1 gamma, anti-PL-7, anti-PL12, anti-Jo1 or anti-SRP have been reported.[77 83 117 184] Electrodiagnostic studies usually reveal myopathic pattern with musculature enhancement may be observed on MRI. Biopsy is often performed and confirms muscle damage with variable degrees of inflammatory and necrotic changes.[81] Of interest, fasciitis is also increasingly reported clinically and seen on MRI findings.[40 76 220–224]

Prompt recognition and early management of myositis is imperative. Discontinuation or at least interruption of CPI was reported in more than 85% of patients and is mandatory in the presence of dyspnoea, bulbar symptoms, severe muscle weakness and/or myocarditis. High-dose systemic glucocorticoids are the first-line treatment, usually 1–2 mg/kg/day (median dosage 70 mg/day). Ten per cent of reported patients received intravenous pulses of methylprednisolone. Up to 20% of patients also received intravenous immunoglobulins,[39 48 77 81–83 181 183–185 188 189 191 198 201 207–209 211 212 220 225 226] and plasma exchanges were performed in around 10% of patients.[48 81 82 117 150 184 188 189 191 197 204 205 226] As second-line therapy, several csDMARDs have been used: mycophenolate mofetil,[77 209 225] methotrexate,[39 44 77 81] azathioprine in one patient but stopped for pancreatitis[77] and hydroxychloroquine in one patient.[76] Six patients have been treated with infliximab, but only one successfully.[82 182 184 225] Importantly, a recent publication reported the resolution of a severe glucocorticoid-refractory myocarditis with abatacept, received after plasma exchanges was unsuccessful.[227] Another T-cell directed therapy, alemtuzumab, has been successfully used in a patient with glucocorticoid-refractory myocarditis.[228] The task force agreed that further evaluation is warranted, most notably on the impact on tumour response; however, due to the lack of effective therapy and the high mortality rate of myositis complicated with myocarditis or severe respiratory failure, one may consider their use as rescue therapy in refractory situations.

9. A pre-existing autoimmune rheumatic and/or systemic disease should not preclude the use of cancer immunotherapy. Baseline immunosuppressive regimen should be kept at the lowest dose possible (for glucocorticoids, below 10 mg prednisone per day if possible). However, many patients may have a flare of the underlying condition and/or immune-related adverse events, requiring the use of glucocorticoids and/or DMARDs (LoE 4; LoA 9).

Ann Rheum Dis: first published as 10.1136/annrheumdis-2020-217139 on 23 April 2020. Downloaded from http://ard.bmj.com/ on February 3, 2023 by guest. Protected by copyright.

Patients with pre-existing inflammatory or autoimmune disease have been largely excluded from clinical trials due to the theoretical risk of worsening autoimmune manifestations. However, there are several series reporting on CPI safety in such patients, with either anti-CTLA-4[229–231] or anti-PD-(L)1 .[77 232–235] Together, a flare of the pre-existing inflammatory or autoimmune disease was observed in half of patients with RA (47/86 patients), PsA (4/8 patients) and myositis (1/2 patients), 64% of patients with PMR (16/25 patients), 31% of patients with SA (4/13 patients) and patients with systemic lupus erythematosus (4/13 patients), 43% of patients with Sjögren's syndrome (3/7 patients), 25% of patients with systemic sclerosis (2/8 patients) and 20% of patients with sarcoidosis (3/15 patients), but less than 10% had to stop CPI therapy during a flare. The patient with pre-existing giant cell arteritis experienced a relapse. There was no flare reported for the few patients with pre-existing seronegative arthritis (n=4), other vasculitis (n=4) and Behçet's disease (n=1). Furthermore, 18 of 104 patients (17%) experienced other irAEs, mainly colitis (n=12), hypophysitis (n=3) and thyroiditis (n=3). One patient with RA developed myositis requiring high dose of glucocorticoids and intravenous immunoglobulins, and another patient with RA developed Sjögren's syndrome with autoantibodies (ANA 1/1280, anti-SSA and SSB). Overall, CPI was discontinued in 8% of patients with pre-existing autoimmune disease due to other irAEs, unrelated to their pre-existing autoimmune disease. In a recent case series of 112 patients with pre-existing autoimmune diseases treated with CPI, a flare of pre-existing autoimmune disease or another irAE occurred in 71% of the patients (47% has a flare of their pre-existing disease and 43% had another irAE).[236] Thus, the occurrence of a flare/irAE was frequent but mostly manageable without CPI discontinuation in 79% of the patients.

In these case series, most flares and irAEs were managed with glucocorticoids, with the need of csDMARDs in some patients, usually hydroxychloroquine, methotrexate, sulfasalazine, either in monotherapy or in combination. The need for TNF inhibitors was only reported in patients with flares of their inflammatory bowel disease flares and in two cases of new-onset colitis. Based on these data, the task force agreed that CPI therapy in patients with pre-existing autoimmune rheumatic and systemic disease was not contraindicated, provided that the patient is well-informed and closely monitored. No preventive treatment is needed. Importantly, this remains a shared decision between the oncologist, rheumatologist and the patient, and whether CPI will be used in a metastatic or adjuvant setting is a major aspect to be considered.

Regarding baseline immunosuppressive regimen, recent preclinical and clinical data highlighted the deleterious impact of baseline glucocorticoids on CPI efficacy, when used at a dosage of greater than 10 mg/day.[163 237] However, this was in patients treated with steroids for their cancer or cancer-related symptoms and not for autoimmune symptoms. Accordingly, the task force agreed on recommending the lowest immunosuppressive regimen possible at the start of CPI therapy. However, future data on prophylactic TNF inhibition and a possible synergistic effect of TNF inhibitors and CPI, reported in a mouse model and currently evaluated in patients, may challenge this statement over time.[171]

10. Before initiation of cancer immunotherapy, there is no indication to test every patient for the presence of autoantibodies. In the case of unexplained rheumatic, musculoskeletal or systemic symptoms, a complete rheumatologic assessment should be performed (LoE 5; LoA 9).

Analysis of pretreatment and post-treatment sera of anti-CTLA4-treated patients with melanoma revealed that for most autoantibodies, including RA-associated antibodies, post-treatment titres increased only marginally and were not associated with the occurrence of irAEs.[238] Similarly, the presence of ANA in serum collected prior to initiating CPI therapy was not found to predict the development of irAEs, except for colitis.[239 240] One study reported divergent data, with pre-existing antibodies independently associated with the occurrence of irAEs, but also with clinical benefits on advanced non-small cell lung cancer.[241] Notably, skin reactions were more frequent among patients with pre-existing RF.

Since autoantibodies are not found in the majority of patients experiencing CPI-induced rheumatic and systemic disease, there is no indication to test every patient at baseline. Of note, the presence of ACPAs has been detected in serum samples obtained prior to CPI therapy in few patients who experienced RA and were asymptomatic before the start of CPI.[78] But this situation might be rare, and the detection of autoantibodies in an asymptomatic patient would not preclude the start of CPI therapy. However, there is the particular situation of patients with thymoma who develop CPI-induced myositis and who all have anti-acetylcholine receptor and antistriated muscle antibodies detected in serum sample obtained prior to CPI therapy.[179] Accordingly, as myositis may evolve into a severe irAE, testing for the presence of these antibodies before starting CPI in a patient with thymoma is recommended to identify a high risk of myositis.

CONCLUSION

These points to consider provide the basis of an European League Against Rheumatism consensus on the diagnosis and the management of rheumatic and systemic irAEs which represent a new and rapidly expanding field. The task force aimed to raise awareness and to assist rheumatologists to improve the diagnosis and the management of patients with irAEs. In contrast to other irAEs, rheumatic irAEs frequently persist over time, specifically inflammatory arthritis was persistent in almost 50% at most recent follow-up with a median of 9 months in a recent study.[169] Thus, irAEs represent a new spectrum of RMDs that rheumatologists should familiarise with. Interestingly, many of these manifestations, either frequent (arthritis, myositis, sicca syndrome) or more exceptionally reported (scleroderma, lupus) are also characteristics of graft versus host disease.[242] Early consultation and strong collaboration between the referring oncologist, the treating rheumatologist, potentially other organ specialists and the patient are all required for optimal irAEs management.

These statements, being based almost entirely on low levels of evidence and on experts opinion, will undoubtedly require updating over the next few years, as new data emerge. Indeed, we expect that future oncological data will likely impact our irAEs therapeutic strategy. We also anticipate a better understanding of irAEs mechanisms and pathophysiology. Finally, multicentre collaborative efforts, prospective registries and randomised trials will help to define the optimal treatment strategies to relieve patient symptoms without altering oncological outcomes.

RESEARCH AGENDA

- To better understand pathophysiology of rheumatic and systemic irAEs.
- To develop information on rheumatic and systemic irAEs for patients starting cancer immunotherapy.
- To define optimal glucocorticoid dose and duration according to the type of rheumatic and/or systemic irAE.
- To assess the effect of different immunomodulatory/immunosuppressive agents already given before the start

Ann Rheum Dis: first published as 10.1136/annrheumdis-2020-217139 on 23 April 2020. Downloaded from http://ard.bmj.com/ on February 3, 2023 by guest. Protected by copyright.

of CPI therapy in pre-existing RMDs on the outcome of immunotherapy.
- To assess the effect of different immunomodulatory/immunosuppressive agents administered for de novo rheumatic and systemic irAEs on the outcome of immunotherapy, using prospective registries.
- To develop well-designed trials on irAE management.
- To assess long-term evolution of rheumatic and systemic irAEs.
- To search for predictive factors for rheumatic and systemic irAEs.
- To revise CTCAE grading of rheumatic and systemic irAEs.
- To obtain insights on the initiation and propagation of classical rheumatic diseases.

Acknowledgements The task force gratefully thank the librarian Catherine Weill (Bibliothèque Inter-universitaire de Santé, Paris, France) for her contribution to the systematic literature search, and European League Against Rheumatism for financial and logistical support.

Contributors The paper was drafted by MK, XM, AF and TS and all authors contributed with specific comments and revisions to the paper.

Funding This study was funded by European League Against Rheumatism (grant no: CLI106).

Competing interests MK: honoraria from Abbvie, BMS, Lilly, Novartis, Pfizer; TRDJR: grants from AbbVie, Takeda, UCB, Janssen, GSK and honoraria from Abbvie, Pfizer, Takeda, Lilly, Medimmune, Novartis, GSK, BMS, AstraZeneca, Janssen; XM: honoraria from BMS; COB: grants and honoraria from BMS and honoraria from Genetech/Roche, Sanofi/Regeneron; OL: grant from Gilead and honoraria from BMS, MSD, AstraZeneca, Janssen; JLe: grants from Novartis, Pfizer and honoraria from Abbvie, AstraZeneca, BMS, Celgene, Hospira, Janssen-Cilag, LEO Pharma, Lilly, MSD, Novartis, Pfizer, Roche, Sanofi, UCB; AM: grants from BMS, Merus and honoraria from Merck Serono, Lytix, BMS, Symphogen, Amgen, AZ/Medimmune, Servier, Gritstone, Pierre Fabre, EISAI, Sanofi; TS: honoraria from Pfizer, Lilly, Novartis, BMS, Abbvie, Sanofi; EHC: grants from Biogen, grants and honoraria from Amgen, Bio-Cancer, Roche, UCB, Pfizer, honoraria from Chugai Pharma, Abbvie, BMS, Celgene, Eli Lilly, Janssen, ObsEva, Regeneron, Sanofi, SynAct Pharma, Tonix, Gilead; LT: honoraria from Novartis; KB: grants from Abbvie, Novartis, Rheumaliga Baden-Württemberg and honoraria from MSD, Abbvie, BMS, Janssen, Lilly, Mundipharma, Novartis, Pfizer, Roche, UCB; KV: speaker fees from BMS; JLa: grants from Aveo and Pharmacyclics, grants and honoraria from Achilles Therapeutics, MSD, Nektar, Novartis, Pierre Fabre, Pfizer, Roche/Genetech and Immunocore, honoraria from AstraZeneca, Boston Biomedical, BMS, Eisai, EUSA Pharma, GSK, Ipsen, Imugen, Incyte, iOnctura, Kymab, Merck Serono, Secarna, Vitaccess and Covance; JBAGH: grants from BMS, Novartis and advisory boards and/or lectures for MSD, BMS, Roche, Novartis; J-EG: grants from BMS, UCB, Pfizer, Sanofi and honoraria from BMS, Lilly, Pfizer, Sanofi-Genzyme, UCB.

Patient and public involvement Patients and/or the public were involved in the design, conduct, reporting or dissemination plans of this research. Refer to the Methods section for further details.

Patient consent for publication Not required.

Provenance and peer review Not commissioned; externally peer reviewed.

Data availability statement All data relevant to the study are included in the article or uploaded as supplementary information

Guidelines

BSR & BHPR, BOA, RCGP and BSAC guidelines for management of the hot swollen joint in adults

G. Coakley[1], C. Mathews[1], M. Field[2], A. Jones[3], G. Kingsley[4], D. Walker[5], M. Phillips[6], C. Bradish[7], A. McLachlan[8], R. Mohammed[9] and V. Weston[10], on behalf of the British Society for Rheumatology Standards, Guidelines and Audit Working Group

KEY WORDS: Septic arthritis, Guidelines, Management.

Scope and purpose of the guidelines

The clinical presentation of a hot swollen joint is common and has wide differential diagnosis. The most serious is septic arthritis, with a case fatality of 11%. Delayed or inadequate treatment leads to joint damage. These guidelines focus on the diagnosis and management of septic arthritis. Hot swollen joints commonly have other underlying diagnoses, including crystal arthritis, reactive arthritis and a monoarticular presentation of polyarthritis.

Guidelines for managing the hot swollen joint in adults

The guidelines have been developed for use with adults who develop a hot swollen native joint acutely (typically with a history of two weeks or less) affecting any joint except the axial skeleton. This is an abridged version, which is available in full as supplementary material on the journal website.

Symptoms and signs suggestive of septic arthritis

(1) Patients with a short history of a hot, swollen and tender joint (or joints) with restriction of movement should be regarded as having septic arthritis until proven otherwise (B).
(2) If clinical suspicion is high, then it is imperative to treat as septic arthritis even in the absence of fever (B).

Investigation of synovial fluid

(1) The synovial fluid must be aspirated, Gram-stained and cultured prior to starting antibiotics (B). Warfarin does not contraindicate needle aspiration (C).
(2) A possibly infected prosthetic joint should always be referred to an orthopaedic surgeon (C).
(3) Neither the absence of organisms on Gram stain nor a negative subsequent synovial fluid culture excludes the diagnosis of septic arthritis (B).
(4) Specimens must be sent fresh to the laboratory and obtained prior to starting antibiotics (C).
(5) Polarising microscopy should always be carried out (B).

Other laboratory investigations

(1) Blood cultures should always be taken (B).
(2) The white cell count, erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) should be measured (B). Inflammatory markers are useful for monitoring response to treatment (B).
(3) The serum urate level is of no diagnostic value in acute gout or sepsis (B).
(4) Electrolytes and liver function should be measured to detect end organ damage because renal function may influence antibiotic choice (B).

(5) If the history suggests non-articular infection, then appropriate cultures and swabs should be taken prior to starting antibiotics (B).

Imaging

Plain radiographs of the affected joint are of no benefit in diagnosing septic arthritis but may show chondrocalcinosis. They should be performed as a baseline investigation (C).

Magnetic resonance imaging is the most appropriate imaging where required, since it is sensitive in detecting osteomyelitis that may require a surgical approach (B).

In suspected hip sepsis, diagnostic aspiration will usually require the use of ultrasound or an image intensifier (C).

Antibiotic treatment of septic arthritis

There is no evidence on which to advise the optimal duration of i.v. or oral antibiotics. Conventionally, they are given intravenously for up to 2 weeks or until signs improve, then orally for 4 weeks. Symptoms, signs and acute phase responses are all helpful in guiding the decision to stop antibiotics. Expert review may be required if the expected resolution does not occur (C).

Summary of recommendations for initial empirical antibiotic choice in suspected septic arthritis

Patient group	Antibiotic choice
No risk factors for atypical organisms	Flucloxacillin 2 g qds i.v. Local policy may be to add gentamicin i.v. If penicillin allergic, clindamycin 450–600 mg qds i.v. or 2nd or 3rd generation cephalosporin i.v.
High risk of Gram-negative sepsis (elderly, frail, recurrent UTI, and recent abdominal surgery)	2nd or 3rd generation cephalosporin eg cefuroxime 1.5 g tds i.v. Local policy may be to add flucloxacillin i.v. to 3rd generation cephalosporin. Discuss allergic patients with microbiology—Gram stain may influence antibiotic choice
MRSA risk (known MRSA, recent inpatient, nursing home resident, leg ulcers or catheters, or other risk factors determined locally)	Vancomycin i.v. plus 2nd or 3rd generation cephalosporin i.v.
Suspected gonococcus or meningococcus	Ceftriaxone i.v. or similar dependent on local policy or resistance
i.v. drug users	Discuss with microbiologist
ITU patients, known colonisation of other organs (e.g. cystic fibrosis)	Discuss with microbiologist

Note: antibiotic choice will need to be modified in light of results of Gram stain and culture. This table is based on expert opinion and should be reviewed locally by microbiology departments. UTI, urinary tract infection; MRSA, methicillin-resistant *Staphylococcus aureus*; ITU, intensive therapy unit.

Joint drainage and surgical options

(1) Septic joints should be aspirated to dryness as often as required (C).
(2) This can be done either through a closed-needle approach or arthroscopically according to local preferences (C).
(3) If the response is not satisfactory with a closed-needle approach, arthroscopic aspiration should be used (C).
(4) In suspected hip sepsis, arrange early referral for an orthopaedic opinion. Urgent open debridement is often necessary (C).

Recommendations specific to primary care and the Emergency Department (ED)

(1) The commonest hot joint to present in primary care is the great toe metatarsophalangeal joint. This is almost always due to gout and can be diagnosed on clinical grounds (B).
(2) Some general practitioners (GPs) regularly aspirate and inject joints. If they aspirate unexpected cloudy fluid from a joint, they should send the sample with the patient to the ED and not inject corticosteroid (C).
(3) GPs and ED doctors should refer patients with suspected septic arthritis to a specialist within the hospital who has the expertise to aspirate the joint (C).
(4) Patients should be admitted to hospital if sepsis is suspected (C).
(5) If there is doubt about whether sepsis might be present, intra-articular steroids should not be used (C).
(6) The skills necessary to aspirate a joint in hospitals will commonly be held by specialists and trainees in ED, orthopaedics and rheumatology (C).

Mechanism for audit of the guidelines

In cases of proven septic arthritis:

(1) Was the joint aspirated at presentation prior to antibiotics? If not, what was the reason?
(2) Was there a delay in treatment and, if so, why?
(3) Was ESR and CRP measured at diagnosis and serially?
(4) Were appropriate cultures taken?
(5) Was the initial antibiotic choice in keeping with the guidelines?
(6) Was prosthetic joint sepsis managed by orthopaedic surgeons?

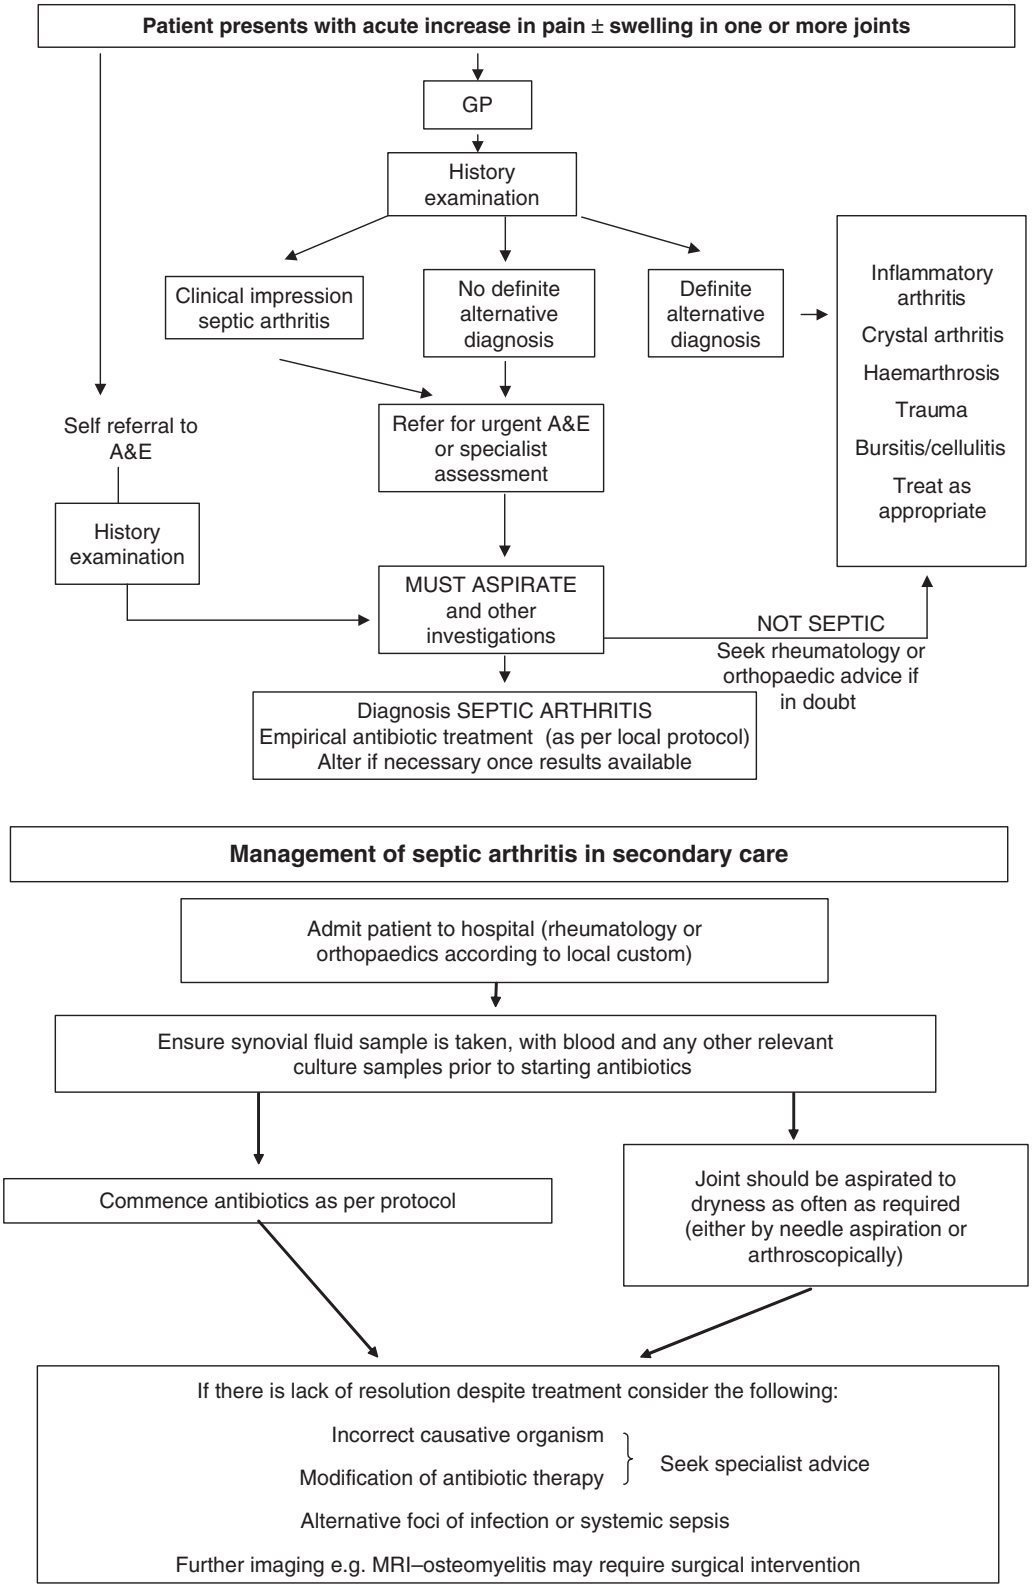
Algorithm of guidelines



Patient presents with acute increase in pain ± swelling in one or more joints
GP
History examination
Clinical impression septic arthritis
No definite alternative diagnosis
Definite alternative diagnosis
Inflammatory arthritis
Crystal arthritis
Haemarthrosis
Trauma
Bursitis/cellulitis
Treat as appropriate
Self referral to A&E
Refer for urgent A&E or specialist assessment
History examination
MUST ASPIRATE and other investigations
NOT SEPTIC
Seek rheumatology or orthopaedic advice if in doubt
Diagnosis SEPTIC ARTHRITIS
Empirical antibiotic treatment (as per local protocol)
Alter if necessary once results available
Management of septic arthritis in secondary care
Admit patient to hospital (rheumatology or orthopaedics according to local custom)
Ensure synovial fluid sample is taken, with blood and any other relevant culture samples prior to starting antibiotics
Commence antibiotics as per protocol
Joint should be aspirated to dryness as often as required (either by needle aspiration or arthroscopically)
If there is lack of resolution despite treatment consider the following:
Incorrect causative organism
Modification of antibiotic therapy
Seek specialist advice
Alternative foci of infection or systemic sepsis
Further imaging e.g. MRI–osteomyelitis may require surgical intervention

The authors have declared no conflicts of interest.
